Abstract. *Stenotrophomonas maltophilia* (*S. maltophilia*) is a difficult-to-treat bacteria. This glucose non-fermenting, multidrug-resistant Gram-negative bacillus is known to cause a range of infections, such as skin manifestations and bacteraemia, with respiratory tract infections being the most common. Patients in intensive care units are often exposed to a higher risk of acquiring an infection caused by this pathogen. Although distinguishing between *S. maltophilia* infections and colonization can be challenging, pneumonia caused by *S. maltophilia* infection is becoming increasingly prevalent. Furthermore, *S. maltophilia* infections are often coupled with *Pseudomonas aeruginosa* infections, reinforcing the need to consider this bacterium as a potential cause of ventilator-associated pneumonia (VAP). The present study describes the case of a 66-year-old male who was diagnosed with VAP due to *S. maltophilia* infection. This condition was effectively treated with trimethoprim/sulfamethoxazole. The case described herein underscores the importance of prompt recognition through heightened clinical suspicion, particularly in patients with VAP who are unresponsive to broad-spectrum β -lactam antibiotics. The early identification of *S. maltophilia* as the root cause of respiratory tract infections can make a significant difference to the outcomes of affected patients.

Introduction

Stenotrophomonas maltophilia (*S. maltophilia*) is a glucose non-fermenting, aerobic, Gram-negative bacillus that is ubiquitously found in aquatic environments and soil (1). Although it is considered a low virulence pathogen, it is increasingly recognised as a main cause of nosocomial infections (2,3).

S. maltophilia, due to his high virulence determinants, including biofilm production, can cause various type of infections, such as skin manifestations and bacteraemia (1), mainly those involving the respiratory tract (4). Major concerns particularly involve vulnerable hosts, such as patients in intensive care units (ICUs) or patients with cystic fibrosis, haematological malignancies, and other significant underlying illnesses (5,6). Moreover, its intrinsic multidrug resistance to several classes of antibiotics poses a major clinical and therapeutic challenge (7).

Historically, trimethoprim/sulfamethoxazole (TMP-SMX) has represented the drug of choice used in the treatment of *S. maltophilia* infections, playing a key role in antibiotic management. However, the emergence of TMP-SMX resistance has already been reported. Other treatment options may include minocycline, tigecycline, levofloxacin, cefiderocol and ceftazidime/avibactam plus aztreonam (8).

The differentiation between *S. maltophilia* infections and colonisation remains challenging, particularly in patients with ventilator devices (1,9). Over the past years, researchers have assessed *S. maltophilia* infections in ICUs, including bloodstream infections, skin and soft tissues infections, urinary tract infections and ventilator-associated pneumonia (VAP), reporting high mortality rates (5,10). Despite its undeniable clinical impact, solid data on *S. maltophilia* are limited compared with other Gram-negative bacteria (11). Moreover, *S. maltophilia* infections are often combined with other bacteria, rendering the clinical picture even more complex (1,11).

The present study, describes the case of a patient with VAP caused by *S. maltophilia* infection, highlighting the challenges in the management of this condition and the importance of prompt recognition and aggressive treatment. Furthermore,

Key words: *Stenotrophomonas maltophilia*, ventilator-associated pneumonia, multidrug-resistant bacteria, *Pseudomonas aeruginosa*, antimicrobial stewardship

the present study highlights the need to consider alternative, effective antimicrobial agent in patients with VAP who are not responsive to broad-spectrum β -lactam antibiotics.

Case report

A 66-year-old male was admitted to the Emergency Department of ARNAS Garibaldi Hospital due to the onset of seizures along with a profoundly altered mental status and fever (maximum temperature, 38°C). His medical history included type 2 diabetes mellitus, hypertension, benign prostatic hyperplasia, dyslipidaemia, and a history of smoking. The patient was taking ertugliflozin, ramipril, alfuzosin and atorvastatin.

Upon admission, the patient was transferred to the ICU and was intubated due to a severely impaired consciousness (Glasgow Coma Scale 8). A brain computed tomography (CT) scan did not reveal any abnormalities.

Lumbar puncture (LP) was performed and empirical antibiotic treatment with intravenous ceftriaxone, acyclovir, ampicillin, and dexamethasone was commenced. The examination of cerebrospinal fluid (CSF) revealed lymphocytic pleocytosis, normal glucose levels and a higher protein concentration. The analysis of CSF using the BIOFIRE® FILMARRAY® Meningitis/Encephalitis (ME) Panel (BioMérieux) yielded positive results for herpes simplex virus 1.

Therapy was continued only with acyclovir at 10 mg/kg three times. The CSF culture tested negative. His chest X-ray was negative (Fig. 1). The blood test results of the patient are presented in Table I.

Despite an initial improvement, 3 days following ICU admission and endotracheal intubation, the patient's clinical condition began to deteriorate, along with worsened respiratory parameters and blood test results (Table I). A chest-CT scan (SOMATOM Definition Flash, Siemens) revealed bilateral basal consolidative opacities, along with bilateral pleural effusion (Fig. 2A).

Due to the diagnosis of VAP, antibiotic therapy was empirically switched to intravenous meropenem at 1 g three times daily plus intravenous linezolid at 600 mg twice daily. *Legionella* and pneumococcal urinary antigens tested negative, as well as a nasopharyngeal swab for severe acute respiratory syndrome-coronavirus 2 (SARS-CoV-2). The analysis of bronchoalveolar lavage (BAL) using the BIOFIRE® FILMARRAY® Pneumonia Panel (PN) (BioFire Diagnostics) tested positive for *Pseudomonas aeruginosa* (*P. aeruginosa*).

At 2 days after switching the therapy, the BAL culture tested positive for *S. maltophilia* on a blood agar plate (Vacutest Kima S.R.L.) (Fig. 3) with a total bacterial count of 10⁵ CFU/ml performed diluting the BAL sample at 1:100 in sterile saline and plating 100 μ l on Muheller Hintong agar (Vacutest Kima S.R.L.). Species identification was assessed using the BD Phoenix system, selecting a colony from the blood agar, and the antibiotic susceptibility test performed using the MIC test strip (Liofilchem) revealed susceptibility to TMP-SMX at an increased exposure [MIC 2 mg/l; according to the European Committee on Antimicrobial Susceptibility Testing (EUCAST), breakpoints are expressed as the trimethoprim concentration]; hence intravenous TMP-SMX at

Figure 1. X-ray image of the patient upon admission.

12 mg/kg (dosing was based on the TMP component) was commenced, while linezolid treatment was terminated.

At 4 days after the addition of TMP-SMX to the treatment schedule, the patient was extubated due to an amelioration in respiratory function and improved blood tests (Table I). The patient's mental status also improved, with no evidence of neurological deficits. The restored consciousness, along with a follow-up brain magnetic resonance imaging (Magnetom, Siemens) not revealing any abnormalities, allowed for the discontinuation of acyclovir administration after 17 days of therapy. Furthermore, due to the resolution of consolidative opacities on a follow-up chest CT scan (Fig. 2B) along with a good general state, the antibiotic therapy with meropenem (14 days of therapy) and TMP-SMX (11 days of therapy) was terminated. Finally, the patient was discharged 7 days after the end of therapy, with no evidence of respiratory or neurological sequelae (Fig. 4).

Discussion

Gram-negative drug-resistant bacteria pose a major threat to physicians due to the increasing incidence of multi-drug resistant (MDR) infections worldwide (12-14), particularly among hospitalised patients (15,16). VAP is a type of pneumonia that occurs >48 h following intubation and is influenced by factors, such as immunosuppression, a long duration of hospitalisation, and prolonged ventilation (17,18).

The SARS-CoV-2 pandemic (19) may have contributed to an increase in the number of cases with VAP, due to the large number of affected patients requiring ICU care and mechanical ventilation (20).

Gram-negative bacilli are the most commonly identified causative agents of VAP, with *P. aeruginosa*, *Enterobacter* spp. and *Klebsiella* spp. being the most prevalent (21,22). MDR Gram-negative infections result in poor outcomes of patients with hospital-acquired pneumonia/VAP and their increasing prevalence makes it crucial for management to consider the local ecology and patient risk factors (15,23). The identification

Table I. Laboratory findings at the time of admission, at the time of VAP diagnosis and following treatment.

| Laboratory parameters (reference range) | At the time of admission | At the time of VAP diagnosis | Following treatment for VAP |
|---|--------------------------|------------------------------|-----------------------------|
| WBC, cells/mmc (4,000-10,000) | 10,330 | 15,100 | 7,200 |
| Neutrophils, % (40-75) | 73 | 85.6 | 57.3 |
| Lymphocytes, % (25-50) | 18.3 | 7.4 | 30.4 |
| Monocytes, % (2-10) | 8.8 | 6.3 | 9.8 |
| Platelets, cells/mmc x10 ³ (150-400) | 150 | 123 | 309 |
| Haemoglobin, g/dl (12-16) | 13.1 | 12.6 | 12.4 |
| AST, UI/l (15-35) | 19 | 17 | 23 |
| ALT, UI/l (15-35) | 24 | 20 | 32 |
| Creatinine, mg/dl (0.8-1.2) | 0.59 | 0.44 | 0.47 |
| Procalcitonin, ng/ml (<0.5) | 0.04 | 0.04 | 0.01 |
| CRP, mg/dl (0-0.5) | 0.5 | 10.5 | 0.07 |

VAP, ventilator-associated pneumonia; WBC, white blood cell count; AST, aspartate aminotransferase; ALT, alanine aminotransferase; CRP, C-reactive protein.

Figure 2. (A) Chest CT scan of the patient at the time of the diagnosis of ventilator-associated pneumonia. Blue stars indicate bilateral basal opacities with pleural effusion. (B) Chest CT scan following treatment with antibiotics. CT, computed tomography.

Figure 3. *Stenotrophomonas maltophilia* colonies on a blood agar plate.

of causative agents of VAP also needs to be a priority, due to the complexity of clinical and therapeutic management (17).

In the case described herein, the patient developed VAP due to *S. maltophilia* infection at 3 days after hospital admission. The categorisation of early- and late-onset VAP, of which late-onset VAP is more likely to be due to a MDR pathogen, is being challenged, as the timing of VAP development needs to be evaluated in the context of other risk factors (24,25).

Although often considered a colonizing pathogen, *S. maltophilia*, an ubiquitous, motile, free-living, aerobic, non-fermenting bacillus, multidrug-resistant Gram-negative bacterium (1), represents the causative agent of various infections, from skin manifestations to bacteraemia (26), particularly in patients with underlying illnesses (6). Recent research has reported that *S. maltophilia*-associated pneumonia

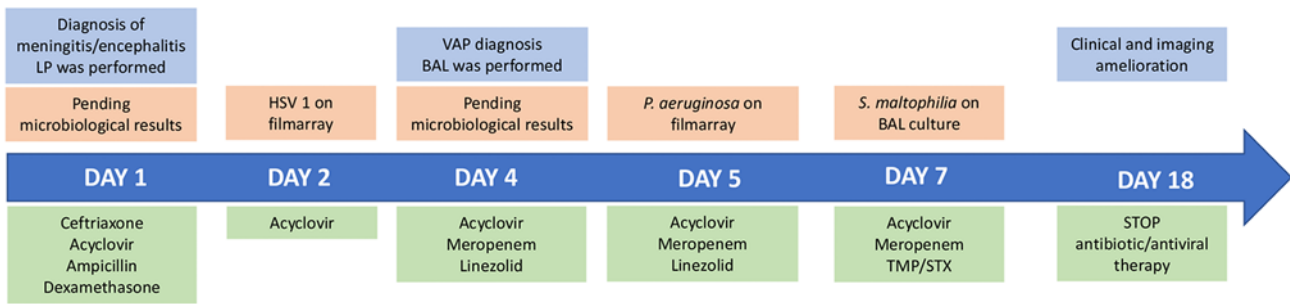

Figure 4. Clinical and therapeutic management timeline. Blue squares represent clinical assessment, pink squares represent microbiological results and green squares represent therapeutic management. LP, lumbar puncture; HSV, herpes simplex virus; VAP, ventilator-associated pneumonia; BAL, bronchoalveolar lavage; TMP, trimethoprim; STX, sulfamethoxazole.

is increasingly being isolated, describing this pathogen as one of the most common infectious agents in patients in ICUs, with a high morbidity and mortality rates. Risk factors for *S. maltophilia*-associated pulmonary diseases include ICU admission and mechanical ventilation, as well as prior broad-spectrum antibiotic therapy, prolonged hospitalization, and immunosuppression (27).

As patients with respiratory tract infections sustained by *S. maltophilia* are usually severely ill and hospitalised, and due to the drug-resistant profile of this bacteria, these conditions often lead to an increase in medical expenses, prolonged durations of hospitalisation and higher mortality rates. Therefore, identifying the right early targeted treatment is the key to reducing the mortality rates associated with *S. maltophilia* infection. A previously published meta-analysis demonstrated that previous carbapenem treatment was associated with lower respiratory tract infections by *S. maltophilia* with the highest odd ratio (OR, 3.69), followed by glycopeptide drugs (OR, 3.22), aminoglycoside drugs (OR, 2.57) and β -lactamase inhibitors (OR, 1.76) (28). That study suggested that when the clinical use of this type of drug is not effective, attention should be paid to the possibility of *S. maltophilia* infection; furthermore it was stated that more types of antibiotics, longer treatment durations and a greater number replacements can significantly increase the risk of respiratory tract infections caused by this bacterium (28).

These data may be explained by *S. maltophilia* features resulting in intrinsic or acquired resistance mechanisms to several antibiotics. Resistance to β -lactams is primarily mediated by L_1 and L_2 , two chromosomal-mediated inducible β -lactamases. L_1 is a molecular class B Zn^{2+} -dependent metallo- β -lactamase, whilst L_2 is a molecular class A clavulanic acid-sensitive cephalosporinase. The *mrcA* gene (encodes penicillin-binding protein 1 α) and regulatory proteins AmpR (transcriptional regulator) and AmpN-AmpG (permease system) influence basal β -lactamase activity. *mrcA* inactivation causes L_1/L_2 β -lactamase hyperproduction (29,30). *S. maltophilia* has demonstrated resistance to aminoglycosides as well, through efflux pumps and aminoglycoside modifying enzyme, such as 6'-N-aminoglycoside acetyltransferases. Fortunately, the new generation cephalosporin, cefiderocol, appears to be able to evade the chromosomally encoded L_1 and L_2 β -lactamases, as demonstrated by the 100% susceptibility of *S. maltophilia* to this molecule (29,30), as well as an *in vivo* model promising efficacy (31). The resistance of *S. maltophilia*

to quinolones is mainly caused by mutations in the *gyrA* and *parC* genes at the target site (QRDRs) of the DNA gyrase enzyme, which is also related to the outer membrane barrier and high-efficiency efflux pump (32,33). Additionally, *S. maltophilia* can accumulate multidrug efflux pumps that reduce tetracycline and fluoroquinolone activity. Increased fluoroquinolone MICs are also observed in isolates that harbour the chromosomal *Smqnr* gene, the determinants of which interfere through binding to gyrase and topoisomerase (1). Furthermore, *S. maltophilia* produces a wide variety of potential virulence factors, such as biofilm and extracellular enzymes, thus rendering treatment challenging (1,5,34).

Despite the lack of definitive evidence on the most effective available treatment, the current IDSA guidelines suggest TMP-SMX as the preferred treatment strategy for mild infections or in combination with another antibacterial agent for moderate to severe *S. maltophilia* infections. To date, combination therapy fails to exhibit evident superiority, with similar rates of clinical efficacy and resistance development compared with monotherapy (7,35), as reported by Shah *et al* (36) in a large retrospective cohort study.

As with other MDR Gram-negative bacteria, such as *Acinetobacter spp.*, for which new antimicrobial agents are intensively being studied due to limited therapeutic options (37-39), *S. maltophilia* poses a major threat, particularly when resistant to TMP-SMX. When TMP-SMX is not a suitable treatment option, due to resistance or patients' intolerance, minocycline, tigecycline, other options include ticarcillin-clavulanate, cefiderocol, or ceftazidime/avibactam plus aztreonam (8).

While interpretive criteria for seven antibiotics have been established by the Clinical & Laboratory Standards Institute (CLSI), EUCAST has only provided breakpoints for TMP-SMX (40).

Of note, isolates resistant to this drug have already been reported (41,42). Previous studies have demonstrated that the *sul1*, *sul2* and *drfA* genes may represent important determinants of TMP-SMX resistance in *S. maltophilia* isolates (1,43,44).

In the case described in the present study, the patient was diagnosed with VAP caused by a strain of *S. maltophilia* with a MIC for TMP-SMX equal to 2 mg/l, the same epidemiological cut-off value reported by the EUCAST. This value is close to the resistance breakpoint (>4 mg/l) and its treatment required an increased exposure to this antibiotic to assure the success of the therapy. This led to the addition of a higher

dose of TMP-SMX. After only 11 days, the patient's condition improved, and the pneumonia had resolved according to a follow-up chest CT scan.

It is worth mentioning that while the IDSA guidelines do not provide specific recommendations on therapy duration, they suggest considering factors, such as the patient's immune status, source control, and treatment response when deciding when to terminate antibiotics (8).

However, the nationwide study by Guerci *et al* (7) found no benefit in prolonged antimicrobial therapy beyond 7 days for patients admitted to ICUs. Nonetheless, the persistence of the infection caused a mistreatment could lead to the development of resistance phenotypes, particularly due to the commonly reported co-infection rate of *S. maltophilia* with other species, and its capability to obtain new resistance genes, such as *sul1* and *sul2*, through horizontal gene transfer (45).

Furthermore, according to previous studies, *S. maltophilia* is often part of polymicrobial infections, with other non-fermenting Gram-negative bacteria, such as *P. aeruginosa*, *Acinetobacter* spp. and *Burkholderia cepacia* complex (2,11). Interactions between these bacteria may play a key role in clinical outcomes, with higher morbidity and mortality rates (46). For example, co-infection with *P. aeruginosa* and *S. maltophilia* has been linked to a higher mortality rate in patients with pneumonia. These two pathogens can form a polymicrobial biofilm in the lungs, interact through quorum-sensing signals and create a favourable environment for each other (47). McDaniel *et al* (48) found that the presence of *P. aeruginosa* facilitated *S. maltophilia* persistence in the lungs during polymicrobial infections.

In the case described herein, the FILMARRAY® test of BAL was positive for *P. aeruginosa*, even though it was not recovered on BAL culture. Given the higher risk of mortality associated with VAP caused by these two pathogens, it was decided to continue treatment with both meropenem and TMP-SMX.

In conclusion, the present study aimed to emphasize the importance of recognizing *S. maltophilia* as a potential pathogen in hospital settings where MDR bacteria are prevalent. The case described herein highlights the common co-occurrence of *S. maltophilia* and *P. aeruginosa* infections, reinforcing the need for considering this bacterium as a potential cause of VAP.

However, inadequate initial antimicrobial treatment is often the norm for *S. maltophilia* infections due to its resistance to commonly used antibiotics such as β -lactams. Thus, the consideration of alternative, effective treatment options for patients with VAP who are not responding to broad-spectrum β -lactam antibiotics is crucial, as well as in patients with *S. maltophilia* identified through bronchoalveolar lavage culture.

Notably however, more research is required in order to better understand the risk factors of VAP caused by *S. maltophilia* and to develop effective prevention strategies and early antimicrobial treatments, ultimately improving the outcomes of patients.
