### Abstract

Guar (*Cyamopsis tetragonoloba* (L.) Taub.) is an annual legume with a long crop cycle and high temperature threshold for seed germination (20-21°C). In semi-arid Mediterranean areas, inadequate soil warmth delays guar planting to May/early June and harvest to October-November, when high rainfall hinders seed maturation and lowers gum quality. Nine world guar genotypes (from India, Pakistan, USA, South Africa) were tested for germination capability and speed in response to temperature. All source seeds were field grown in Sicily for use in germination assays. The following temperature regimes were imposed adopting a completely randomized design: A) seven constant temperatures from 5°C to 35°C (5°C increments), and B) two alternating temperatures of 15/10°C and 20/15°C (6h/18h thermoperiod), each consisting of four replicates of 25 seeds. Optimal germination temperatures were always 30 and 35°C, but Indian genotypes also demonstrated substantial germination percentages (33-43%) at constant temperatures as low as 15°C. Mean germination time (MGT) of genotypes India2, Kinman, Lewis, and Monument were 1.1 to 1.7 days at 30 and 35°C. At lower temperatures (15°C), the germination percentage and MGT improved significantly when the seeds were exposed at 20°C for 6 hours a day. In particular, Kinman, India2 and Monument gave good results, achieving 80%, 76% and 66% germination, respectively, with MGTs of 5 days. This alternating temperature regime is typical in soil during the Mediterranean spring. Results may be useful both for farmers to identify optimum timing for guar sowing, and for breeders to cross genotypes that tolerate low germination temperatures with high yielding genotypes.

**Keywords:** Guar, seed germination, mean germination time, genotypes, constant temperature, alternating temperature.

### Introduction

Guar (*Cyamopsis tetragonoloba* (L.) Taub.) is a low-input annual legume species (Gresta et al., 2014), with a spring-summer cycle, mainly grown in India (80% of the world's production), Pakistan (15%), Sudan and the United States (Sharma, 2010). It is a self-pollinated crop, extremely drought-tolerant, with good adaptability to a wide range of soil conditions, even though it performs best in sandy soils. It tolerates salinity and low fertility soils (Ashraf et al., 2002; Ashraf et al., 2005) and is an excellent soil-building crop due to potential *Bradyrhizobium* nodulation or other crop rotation benefits (Elsheikh and Ibrahim, 1999; Tripp et al., 1977).

Guar has long been cultivated as a vegetable, green manure and forage crop mainly in South Asia. From the 1950's it has assumed an important role among industrial crops since it has been adopted as the substitute for carob in the paper industry (Abidi et al., 2015). In fact, the galactomannans extracted from the endosperm show

thickening, stabilizing, sizing and strengthening properties and they improve handling, viscosity and shelf life of numerous materials including industrial products and foods, even at low concentrations and low temperatures (Mathur 2012). Currently, guar galactomannans are used in many industrial activities, such as food, paper, explosives, textiles, oil well drilling and fracking, cosmetics and pharmaceutical industries (Abidi et al., 2015; Mudgil et al., 2014; Vaughn et al., 2011; Lubbe and Verpoorte, 2011). Moreover, after the extraction of the endosperm, the by-product is considered a valuable feed supplement for animals due to its high protein content (Chiofalo et al., 2018; Gresta et al., 2017).

Previous research demonstrates the adaptability of guar to irrigated Mediterranean environments (Sortino and Gresta, 2007; Gresta et al., 2014; Gresta et al., 2016a), although some obstacles remain for widespread cultivation on a field scale. One of the main problems in these environments is

the excessive length of the crop cycle, which may take more than 160 days, in the case of late genotypes.

Moreover, guar needs high soil temperatures of at least 20–21°C for adequate seed germination, while the optimal temperature is considered 30°C (Undersander et al., 1991). In Mediterranean areas, such temperatures impose a sowing time no earlier than May–early June (Gresta et al., 2013), thus harvest is delayed until November, after a rainy period in late summer/early autumn. Consequently, late autumn rain may cause increased blackening of seeds, which results in a potentially significant decrease in yield, seed gum quality and commercial value (Liu et al., 2007). Moreover, such a late harvest does not fit in well with the typical Mediterranean crop rotation systems, which are frequently based on autumn sown wheat and other cereals.

A possible way to overcome the above-mentioned problems could be selection of genotypes with lower temperature requirements for germination. In fact, genotypes with good germination ability at 15°C would permit sowing at the beginning of April and, consequently, anticipate harvest at least 30 days sooner, in a more favorable time of the year.

Temperature is one of the main environmental factors affecting seed germination. Previous studies have shown wide inter-specific and intra-specific variability in terms of base temperature and optimal temperature levels. Furthermore, threshold temperatures may also change in response to temperature regimes, depending on the existence and amplitude of daily fluctuations (Probert, 1992; Kigel, 1995).

Despite its widespread importance as an industrial crop, guar has received little attention from the research community, including aspects related to seed germination. Image analysis has been conducted on guar seed (Gresta et al., 2016b), but without giving any information on how imaging results might describe germination ability. A few guar germination trials have been conducted for the assessment of seed germination capability (Iqbal, 2015; Teolis et al., 2009; Ramarajan et al., 2013). Therefore, the objective of the present research was to test nine different world guar genotypes with respect to their germination behavior at seven constant temperatures plus two alternating temperature cycles, focusing on the key temperatures that could allow earlier sowing in semi-arid Mediterranean-type environments.

## Results and Discussion

### *Germination at constant temperature from 5°C to 35°C*

Germination was significantly affected by genotype, temperature and their interaction (Figure 1). No germination was observed at 5 and 10°C for all genotypes. For Kinman, Lewis and South Africa, negligible or no germination was observed at 15°C. Germination increased sharply in Kinman and Lewis, from less than 5% at 15°C to 98% and 68%, respectively, at 20°C. For the other genotypes, the temperature-dependent increase in germination percentage was more gradual: germination in Indian genotypes, Monument and Pakistan showed moderate germination (from 25 to 50%) at 15°C, and further increase in germination at higher temperature, reaching over 75% germination. Matador and South Africa showed a contrasting pattern with a low increase at 15°C, reaching the

maximum percentage of germination at 30°C, with values no higher than 80% (Fig. 1).

For all genotypes, maximum germinated percentages were obtained at 25°C or 30°C, reaching values up to 100%. Pakistan and Matador showed a strong decrease in germination at 35°C, while all other guar genotypes were less hindered by the highest temperature.

It is widely known that temperature has a strong effect not only on germination capability, but also on germination speed, which is an important parameter for field sowing. Mean Germination Time (MGT) decreased as temperature increased from 15°C to 30°C and, for some genotypes, to 35°C (Figure 2). High MGTs (over 20 d), which indicate slow germination, were observed in South Africa (23.2 d ± 1.8), Monument (21.2 d ± 1.6) and Kinman (20.5 d ± 2.2) at 15°C. Also at 15°C, intermediate MGTs were observed in Indian genotypes (17.2 d, on average), while the shortest MGT, which corresponds to fast germination, was observed in Matador (12.1 d ± 0.9), which showed also the shortest MGT at higher temperatures, with values of 1.2 d ± 0.1 and 0.6 d ± 0.04 at 25 and 35°C, respectively.

Favorable MGTs at 30 and 35°C ranged from 1.0 to 2.3 d in Kinman, Monument, India2, Lewis, Pakistan, India1 and India3. Contrarily, at 30°C and 35°C, South Africa showed higher MGTs (6.5 d ± 0.5 and 5.0 d ± 0.4). Our data are in partial agreement with those of Undersander et al. (1991) who reported a threshold soil temperature for seed germination equal to 21°C and an optimal temperature equal to 30°C. The same information is reported by Faridah-Hanum and van der Maesen (1997) and Hymowitz and Matlock (1964). In our trial, some genotypes were also able to germinate at less than 20°C, though with low germination capability and speed. In fact, all three Indian genotypes, and to a lesser extent, Monument, Pakistan and Matador germinated at 15°C, with germination percentages ranging from 20% to 43%.

Relating to optimum germination temperature, Hu et al. (2002) suggested that the temperature at which guar seed germinates most quickly is 27°C. Vinisky and Ray (1985) found no differences in guar germination responses at four temperatures between 25°C and 37°C, but they found a significant temperature-salinity interaction, reporting a severe decrease in germination with the combination of high temperatures (34°C and 37°C) and high salt concentrations (-1.1 and -1.5 MPa). Our data are also in agreement with Liu et al. (2007) who tested three guar genotypes (including Lewis) at 22 °C under dark conditions where they obtained germination between 85 and 95%. Working with 41 accessions (including Kinman and Lewis) in a germination trial in the dark at 20/21°C, Teolis et al. (2009) obtained germination percentages always over 90%, except for one of the two Lewis accessions (85%).

### *Germination at two alternating temperature regimes (15/10 and 20/15°C)*

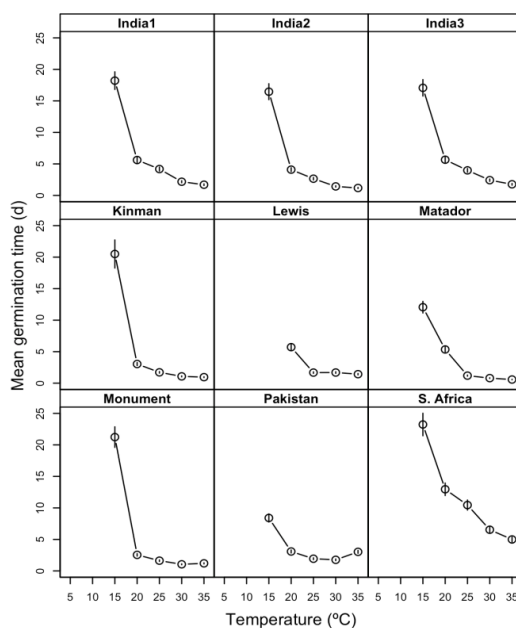

In contrast to constant temperatures, guar genotypes showed a completely different behavior at alternating temperatures. At 15/10°C, negligible germinations were observed: 4% in India2 and 2% in Matador (data not shown). On the other hand, at 20/15°C, Kinman, India2, and Monument showed germination percentages over 60% (Fig 3). The capability of germination for these three genotypes

**Table 1.** Origin of the nine guar genotypes planted in Plain of Gela, Sicily, 2012.

Genotypes	Origin	Growth Habit
India 1	India	Single stem
India 2	India	Single stem
India 3	India	Single stem
Kinman	Texas (USA)	Branching
Lewis	Texas (USA)	Fine branching
Matador	Texas (USA)	Branching
Monument	Texas (USA)	Single stem
Pakistan	Pakistan	Branching
South Africa	Pakistan	Wide branching

**Fig 1.** Percentage of germinated seeds for nine world guar genotypes, after 25 days in a darkened growth chamber at fixed temperatures ranging from 5°C to 35°C. Source seed was grown in the Plain of Gela, Sicily, 2012. Vertical bars represent SEs.

**Fig 2.** Mean germination time (MGT) of nine world guar genotypes assessed for 25 days at constant temperatures ranging from 5°C to 35°C. Vertical bars represent SEs. No MGT was calculated for any Petri dish with less than 10% of final percentage of germinated seeds.

**Fig 3.** Percentage of germinated seeds for nine world guar genotypes, after 25 days in a darkened growth chamber at alternating 20°C/15°C (6/18 h). Vertical bars represent SEs. Bars with different letters are significantly different ( $P < 0.05$ ).

**Fig 4.** Mean germination time (MGT) of nine world guar genotypes assessed at alternating temperatures 20°C/15°C (6/18 h) for possible earlier spring planting under cooler soil conditions. Vertical bars represent SEs. Bars with different letters are significantly different ( $P < 0.05$ ).

was not as high as at constant 20°C, but germination was much higher than at constant 15°C. Apart from the above mentioned three varieties, germination above 40% was observed also in India1, India3, Lewis and Matador, while in Pakistan and South Africa a lower germination (28 and 20%, respectively) was recorded. As expected, MGTs at 20/15°C were high, but suitable for an earlier spring field sowing (Fig 4). The lowest MGT values were observed in Matador, Kinman, Monument, Pakistan and India2 (5.0 d  $\pm$  0.4, on average). A greater MGT was measured in India1 and India3 (7.0 d  $\pm$  0.5, on average), Lewis (7.4 d  $\pm$  0.6) and South Africa (9.8 d  $\pm$  0.8). Considering the thermal period adopted for this experiment, results suggest that it is possible to obtain

adequate germination and crop establishment by sowing early in spring, if 20°C is reached for 6 hours a day. In this respect, matching high germination values with low mean germination times, we suggest that Kinman and India2 might be the best options, having reached 80% and 76% of germination in 5 days. With these varieties, although at the cost of using higher seeding rates, the sowing date may be anticipated, by exploiting the time-window when daily soil temperature highs are between 15°C and 20°C. This information could be useful for those farmers who want to explore the possibility of an early guar sowing, to better fit in with their cropping systems.

No germination trials at alternating temperatures have been reported for guar in the literature. Compared to cool-season legumes, such as *Scorpiurus* spp. (Gresta et al., 2007a), annual medics (Gresta et al., 2007b) and *Lotus* spp. (Gresta et al., 2011), guar showed a much lower degree of hard seed, but a clearly higher threshold temperature for seed germination. Furthermore, compared to soybean and other warm-season legumes, guar exhibited a higher germination temperature; indeed, with respect to guar, some varieties of soybean were able to germinate at lower temperatures (10°C and 15°C), reaching up 54-62% germination at 10°C (Brar et al., 1991; Butler et al., 2014). On seven annual warm-season and eleven annual cool-season legumes, Butler et al. (2014) found that germination of warm-season legumes tended to be maximized at 25°C, while the germination of cool-season legume was greatest from 10 to 25°C. The optimal temperature for both germination and seedling growth are adaptive traits to the environment of origin of the species (Motsa et al., 2015). For this reason, guar show best germination at high day-time temperatures, which are characteristic of tropical and subtropical regions.

## Materials and methods

### Plant materials

The trial was conducted in 2013 on nine guar genotypes originating from different world sources (Table 1).

Genotypes were chosen following those tested in the Mediterranean environment by Gresta et al. (2016a). The American varieties (Kinman, Lewis, Matador and Monument) were supplied by the Texas A&M Agrilife Extension Service. India1, India2 and India3 are Indian genotypes and were purchased from an international seller, who was unable to provide any detail about their characteristics or genetic background. However, these genotypes are marketed for planting seed in Rajasthan, India. A Pakistan genotype was also obtained and included in the experiment. Finally, a well-adapted genotype grown in South Africa was included, though it also originated in Pakistan.

To avoid any possible effect deriving from stress experienced by the seeds during maturation on the mother plant in the environment of origin, the nine genotypes were sown in the beginning of May 2012 in the Plain of Gela (60 m a.s.l., 37°03'01"N, 14°20'25"E), Sicily, Southern Italy. The Plain of Gela is a suitable Mediterranean environment for guar cultivation since it is characterized by hot summers and moderate water availability. In 2012, air temperature ranged from 11.5°C in February to 29.2°C in August; total rainfall was 532 mm, 95% of which concentrated in January-April and September-December. Weeds were controlled with pendimethalin and imazamox as recommended for grain legumes (Avola et al., 2008). The plots were fully irrigated, with approximately 2,500 m<sup>3</sup> ha<sup>-1</sup>, to avoid any problems due to water stress. They were hand harvested in October, when the seeds were fully mature. Immediately after harvest, intact seeds were selected, packed and stored in a refrigerator at 4°C for three months.

### Experimental design and germination tests

Nine treatments (seven at constant and two at alternating temperatures) consisting of 4 replicates of 25 seeds each,

were arranged in a completely randomized design. Seeds were placed on Whatman No. 3 filter paper in 9 cm Petri dishes. The Petri dishes were incubated in thermostatically controlled germination chambers (Sanyo – model MLR-35H, Tokyo, Japan). The paper sheet was soaked with 5 ml of distilled water at the beginning of the test, and replenished as needed in the following days. To explore the effect of temperature on seed germination, seven treatments of different constant temperatures were initiated from 5°C to 35°C ± 1°C in increments of 5°C in continuous darkness to simulate soil conditions at sowing. In order to simulate the daily trend of soil temperatures during the guar sowing time in Mediterranean regions, two additional treatments with alternating temperatures (15/10°C and 20/15°C for 6/18 hours thermal period) under dark were imposed. The dark treatment was imposed by wrapping Petri dishes with a double layer of aluminum foil.

In order to ascertain seed viability for germination testing, the seed coat of an extra seed-lot for each variety was scarified by abrasion with sand paper and tested in preliminary germination assays at 30°C (optimal temperature, Undersander et al., 1991). The presence of abrasion was confirmed with a microscope, and all scarified seeds germinated.

Germination dishes were monitored daily for 25 days, and seeds with visible radicle protrusion (exceeding 2 mm) were counted and removed from the Petri dishes. The seeds under dark conditions were monitored with a green safety light to eliminate red-far red light effects on seed germination.

Non-viable seeds were identified based on their softness and brownish color and were not considered in data analyses. Seeds infected by fungi were considered as not germinated. No fungicide treatment was used to avoid possible interference of the active ingredient on germination of seeds.

### Data collection and statistical analyses

At the end of the trial, the Final Germinated Percentage (FGP) for each Petri dish was calculated from the total number of seeds germinated divided by the total number of viable seeds tested and multiplied by 100.

Speed of germination was also determined by considering the mean germination times (MGTs), i.e. the average value of the time to germination for all germinated seeds in each Petri dish. MGTs were derived from Kaplan-Meyer estimators of germination curves with mid-point imputation (Law and Brookmeyer, 1992). These estimators are similar to traditional MGT estimators (Ranal and Santana, 2006), although they are preferable as they can more reliably account for all types of uncertainty in measuring germination times for each seed in the lot (Onofri et al., 2010). No MGT was calculated for any Petri dishes with less than 10% of FGP.

For FGPs, the corresponding proportion was analyzed using a Generalized Linear Model with binomial error and logit link. The significance of genotype and temperature effects, as well as their interaction was tested by using Wald-tests. Back-transformed percentages were derived together with delta standard errors and they were reported in graphs (Faraway, 2006).

For MGTs, data were log-transformed and submitted to ANOVA, to test the significance of the above-mentioned

effects. Back-transformed means together with delta standard errors are reported in the Figures. Differences between back-transformed means were tested by using the general procedure suggested in Hothorn et al. (2008), together with a single-step multiplicity adjustment.

## Conclusion

In conclusion, this research suggests that, even though minimal threshold germination temperature for guar is considered 20°C, some genotypes such as Indian (33-43%) and, to a lesser extent, Pakistan and Monument (27-28%) showed limited germination even at constant temperature of 15°C. Optimal temperatures range from 25 to 35°C. Furthermore, alternating temperatures (20/15°C, 6/18h) as commonly found in soil in the Mediterranean environment at the beginning of April strongly enhance germination compared to a constant temperature of 15°C: in this case, it was possible to reach high germination percentages in Kinman (80%), India2 (76%) and Monument (66%). The results of this trial could be helpful for researchers and farmers to better understand opportunities for early spring sowing in relation to temperature and could be exploited also for breeding purposes, crossing genotypes that tolerate low germination temperatures with high yielding genotypes.
