**Background:** The aim of this open label phase II study (NCT00407459) was to assess the activity of the vascular endothelial growth factor (VEGF) inhibitor bevacizumab combined with pemetrexed and carboplatin in patients with previously untreated, unresectable malignant pleural mesothelioma (MPM).

**Methods:** Eligible patients received pemetrexed 500 mg m<sup>-2</sup>, carboplatin area under the plasma concentration–time curve (AUC) 5 mg ml<sup>-1</sup> per minute and bevacizumab 15 mg kg<sup>-1</sup>, administered intravenously every 21 days for six cycles, followed by maintenance bevacizumab. The primary end point of the study was progression-free survival (PFS). A 50% improvement in median PFS in comparison with standard pemetrexed/platinum combinations (from 6 to 9 months) was postulated.

**Results:** Seventy-six patients were evaluable for analysis. A partial response was achieved in 26 cases (34.2%, 95% CI 23.7–46.0%). Forty-four (57.9%, 95% CI 46.0–69.1%) had stable disease. Median PFS and overall survival were 6.9 and 15.3 months, respectively. Haematological and non-haematological toxicities were generally mild; however, some severe adverse events were reported, including grade 3–4 fatigue in 8% and bowel perforation in 4% of patients. Three toxic deaths occurred.

**Conclusion:** The primary end point of the trial was not reached. However, due to the limitation of a non-randomised phase II design, further data are needed before drawing any definite conclusion on the role of bevacizumab in MPM.

Malignant pleural mesothelioma (MPM) is an aggressive tumour with a poor prognosis. Only a minority of patients are eligible for multimodality therapy including surgery (Tsao *et al*, 2009; Scherpereel *et al*, 2010). Following the results of a large phase III trial, the combination of cisplatin and pemetrexed has been established as the standard of care for unresectable MPM

(Vogelzang *et al*, 2003). Carboplatin has the potential advantages of a better side effect profile and ease of administration. The combination of pemetrexed and carboplatin was found to be synergistic in preclinical models and active and well tolerated in a phase I trial as well as in two large phase II studies (Hughes *et al*, 2002; Ceresoli *et al*, 2006; Castagneto *et al*, 2008). These data were

confirmed by the results of an International Extended Access Program (Santoro *et al*, 2008). Unfortunately, nearly all MPM patients progress during or after first-line treatment. Second-line chemotherapy is being increasingly used in clinical practice, but to date there is no standard approach for this growing population of patients (Ceresoli *et al*, 2010). As a whole, currently available therapies still appear to have modest results, and new treatment strategies are eagerly awaited.

Preclinical studies have clearly shown that angiogenesis has a key role in the biology of MPM (Zucali *et al*, 2011). Vascular endothelial growth factor (VEGF) stimulates MPM cells growth *in vitro* in a dose-dependent manner and this growth has shown to be inhibited by anti-VEGF antibodies (Strizzi *et al*, 2001). Malignant pleural mesothelioma patients have among the highest circulating VEGF levels of any solid tumour, and high VEGF levels represent a poor prognostic factor in this disease (Kumar-Singh *et al*, 1999; Yasumitsu *et al*, 2010). Angiogenesis inhibitors, particularly bevacizumab, have therefore been studied and are still under evaluation in several trials in MPM, both in the first-line and in the pretreated patient setting (Ceresoli and Zucali, 2012). The results of a multicentre, double-blind, placebo-controlled randomised phase II trial of cisplatin–gemcitabine plus bevacizumab or placebo in patients with MPM have been recently reported (Kindler *et al*, 2012). In that study, the addition of bevacizumab did not significantly improve response rate, progression-free survival (PFS) or overall survival (OS). Another multicentre single-arm phase II study of the combination of cisplatin and pemetrexed plus bevacizumab in MPM patients failed to meet the primary end point of a 33% improvement in PFS rate at 6 months compared with historical controls treated with cisplatin and pemetrexed alone (Dowell *et al*, 2012).

We report here the final results of a multicentre, open label phase II study designed to explore the efficacy of the combination of pemetrexed and carboplatin with bevacizumab as front-line therapy in patients with unresectable MPM.

## PATIENTS AND METHODS

**Patient selection.** Patients were eligible if they had histologically proven MPM and unresectable disease according to an MPM-experienced surgeon. The presence of measurable and/or evaluable lesions according to modified RECIST criteria (Byrne and Nowak, 2004) was mandatory. Eligibility criteria included age > 18 years and Eastern Cooperative Oncology Group (ECOG) performance status (PS) ≤ 1. An adequate bone marrow reserve was required, with absolute neutrophil count ≥ 1.5 × 10<sup>9</sup> per litre, platelets ≥ 100 × 10<sup>9</sup> per litre and haemoglobin ≥ 9 g dl<sup>-1</sup>. Creatinine clearance, calculated by the Cockcroft and Gault formula, had to be ≥ 50 ml min<sup>-1</sup>, bilirubin ≤ 1.5-fold the upper limit of normal (ULN), and alanine aminotransferase or aspartate aminotransferase ≤ 2.5-fold ULN. A baseline urine dipstick with proteinuria < 2+ was required. Patients discovered to have ≥ 2+ proteinuria had to undergo a 24-h urine collection and demonstrate ≤ 1 g of protein per 24 h. Prior systemic or intracavitary chemotherapy, documented brain metastases, serious comorbidities or other malignancies were not allowed. Patients with uncontrolled hypertension, serious non-healing wound or ulcer, evidence of bleeding diathesis or coagulopathy, or major surgical procedure, open biopsy, or significant traumatic injury within 28 days before study treatment start were not eligible for the trial. Patients were also excluded if they were currently on treatment with anti-coagulants, high-dose aspirin (> 325 mg day<sup>-1</sup>) or other medications known to predispose to gastrointestinal ulceration.

The study was conducted after approval by the ethical review board of each participating centre. Recommendations of the

Declaration of Helsinki for biomedical research involving human subjects were also followed. Written informed consent was obtained from each patient before entering the study.

**Study design.** The study was planned as a multicentre, open label phase II trial of the combination of pemetrexed, carboplatin and bevacizumab as front-line treatment in patients with MPM. Patients were enrolled prospectively from 10 Italian Institutions. The primary end point of the study was PFS. Secondary end points included toxicity, response rate and OS, as well as the evaluation of PFS and OS according to pretreatment serum VEGF levels. The trial was registered at [www.clinicaltrials.com](http://www.clinicaltrials.com), with the number NCT00407459.

**Treatment.** Pemetrexed was administered intravenously at a dose of 500 mg m<sup>-2</sup> over 10 min, followed by carboplatin, administered over 1 h intravenous infusion at an area under the plasma concentration–time curve (AUC) of 5 mg ml<sup>-1</sup> per minute and by bevacizumab, delivered as a 15 mg kg<sup>-1</sup> intravenous infusion. Bevacizumab was administered initially over a 90-min period. If the first infusion was well tolerated, then all subsequent infusions were delivered over 30 min.

All drugs were given on day 1, every 21 days. Treatment was repeated for a maximum of six cycles or until progression or unacceptable toxicity. Patients without disease progression and/or severe toxicities received maintenance bevacizumab for a maximum of 1 year. All patients received during chemotherapy standard supplementation with folic acid and vitamin B<sub>12</sub>. Dexamethasone, at a dose of 4 mg twice daily, was given orally the day before, the day of, and the day after each chemotherapy. Salicylates and non-steroidal anti-inflammatory agents were not allowed the 2 days before, the day of, and the 2 days after treatment. Standard anti-emetic prophylaxis with intravenous 5-HT<sub>3</sub> antagonists was used.

Dose adjustments at the start of a subsequent cycle of therapy were based on haematologic and non-haematologic toxicity observed during the preceding course, according to protocol-specified guidelines. Dose delays up to 42 days were permitted to allow recovery from toxicity.

**Patient assessment.** Baseline assessment included a complete medical history and physical examination, complete blood cell counts and chemistries, and creatinine clearance. A chest and abdomen CT scan was performed at baseline and repeated every two cycles until the end of chemotherapy and every three cycles during maintenance bevacizumab. Best tumour response was evaluated according to modified RECIST criteria for mesothelioma (Byrne and Nowak, 2004). When response was documented at first assessment after two cycles, a confirmatory scan was needed after 4 cycles. A blood sample was obtained in a subset of patients to determine basal serum VEGF level (R&D Systems, Quantikine Human VEGF, Minneapolis, MN, USA). Treatment toxicity was evaluated according to the NCI Common Toxicity Criteria (CTC) version 3.0 grading system. After completion of the study treatment, patients were evaluated every 3 months with chest and abdomen CT scans until disease progression, and then followed up for survival until death or last contact if still alive. Data on second-line therapies were systematically collected. Progression-free survival was defined as time from first day of study treatment until time of patient progression (as shown by radiological or clinical examination) or death from any cause. Patients without any evidence of progressive disease were censored at the date of the last follow-up. Overall survival was calculated as the time from first day of study treatment until death from any cause; patients who were alive on the date of last follow-up were censored on that date. For the final analysis, follow-up was closed at April 2012. All the data were centrally reviewed after study conclusion.

**Statistics.** A single-arm, single-stage non-parametric survival design was adopted. For median survival, a Brookmeyer–Crowley like test was assumed (Karrison, 1995). Considering a median PFS of 6 months, an increase of 50% in the median survival, that is, from 6 to 9 months, was considered clinically worthwhile. Setting  $\alpha$  equal to 0.10 and  $\beta$  equal to 0.15, the number of patients to be enrolled was 77. Data were described as frequencies and percentages, or as median and range when appropriated. Ninety-five percent confidence intervals for response rates were calculated. Actuarial survival curves were generated using the method of Kaplan and Meier (1958). Median follow-up was estimated with the use of the inverse Kaplan–Meier method (Schemper and Smith, 1996). The PFS and OS were analysed according to the following variables: age, gender, histology, ECOG PS, European Organization for Research and Treatment of Cancer (EORTC) prognostic model for MPM (Curran *et al*, 1998) and, in a subgroup of patients, baseline serum VEGF levels. The EORTC prognostic score stratifies MPM patients in good- and poor-prognosis subgroups. Poor prognosis is associated with poor ECOG PS, high WBC count, male sex, probable diagnosis of MPM and sarcomatous histology (Curran *et al*, 1998). The independent value of variables was assessed in multivariate analysis using the Cox proportional hazard regression model, with an estimate of hazard ratios (HRs) (Cox, 1972). All probability values were two sided. Statistical analyses were performed using the software R, version 2.0.1 (R Foundation for Statistical Computing, Institute for Statistics and Mathematics, Wien, Austria).

## RESULTS

**Patient characteristics.** Between September 2007 and October 2009, a total of 77 patients entered the study. One patient had a concomitant diagnosis of acute myeloid leukaemia before treatment start, and did not receive any study treatment. He was therefore excluded from efficacy and toxicity analysis. The characteristics of the study population are summarised in Table 1.

**Efficacy.** Best tumour response was assessed in 76 patients. Twenty-six patients experienced a partial response, for an objective response rate of 34.2% (95% CI 23.7–46.0%). Response was achieved in patients with epithelioid or mixed histotype only. Median duration of partial response was 8.0 months (range, 3.7–25.8 months). Forty-four patients (57.9%, 95% CI 46.0–69.1%) achieved stable disease and 6 (7.9%) were considered to have disease progression. Overall, 70 patients (92.1%) achieved a disease control (95% CI 83.6–97.1%).

With a median follow-up of 34.4 months (range 1.1–44.5 months), 11 patients were still alive, 2 of them without any evidence of disease progression at 25.9 and 44.5 months. Figure 1 shows the actuarial PFS curve for the entire population; the median PFS was 6.9 months. The 1-year and 2-year estimates were 25.4% (95% CI: 16.2–35.6%) and 8.0% (95% CI 3.2–15.5%), respectively. The OS curve for all enrolled patients is shown in Figure 2. The median OS was 15.3 months; the 1-year and 2-year estimates were 62.6% (95% CI: 50.7–72.5%) and 25.9% (95% CI: 16.6–36.2%), respectively. Patients receiving at least four treatment cycles ( $n = 65$ , 85.5%) had a median PFS and OS of 8.0 and 17.6 months, respectively.

In the univariate model, a longer PFS was significantly related to epithelioid histology ( $P < 0.039$ ) and good EORTC score ( $P = 0.043$ ). A longer OS was associated with an epithelioid histology ( $P = 0.024$ ), a good EORTC score ( $P = 0.006$ ), and with ECOG PS of 0 ( $P = 0.033$ ). All patients surviving longer than 2 years had a good EORTC prognostic score. However, in the multivariate model, none of the analysed variables were significantly related to either PFS or OS.

<sup>a</sup>Twenty-six patients (34.2%) were 70 years or older.

Figure 1. Kaplan–Meier curve of progression-free survival for all patients ( $n = 76$ ; median 6.9 months).

**Study drugs administration and toxicity.** Patients received a median of six cycles of chemotherapy (range 1–6) plus bevacizumab; 65 (85.5%) completed at least four cycles. Forty-eight patients (63.1%) started maintenance bevacizumab, which was continued for a median of seven cycles (range 1–18). In two cases, maintenance bevacizumab was continued beyond 1 year (for 31 and 47 cycles, respectively), based on treating physician's decision. Dose reductions were uncommon.

Haematological toxicity was mild and consisted mostly of neutropaenia (Table 2); febrile neutropaenia was observed in two patients. Non-haematological toxicity was generally mild (Table 2); nausea/vomiting, fatigue, mucositis (stomatitis and conjunctivitis), hypertension and constipation were the most commonly reported

adverse effects. Some severe adverse events probably related to bevacizumab were observed, as a grade 3 pulmonary embolism, a severe gastro-intestinal bleeding, and three cases of bowel perforation in three elderly patients (75, 76 and 78 years old, respectively) without evidence of abdominal involvement by disease, or history of major abdominal surgery or comorbidities. However, all these patients had a history of diverticular disease, asymptomatic at enrollment.

Three toxic deaths occurred, one in a patient with bowel perforation, the second in a patient who died for pneumonitis with a documented H1N1 viral infection, and the third in a patient who died suddenly at home 2 weeks after the last treatment administration (autopsy was not performed). Another patient who suffered from bowel perforation died while progression free at 5 months due to complications of intestinal reconstruction.

Figure 2. Kaplan–Meier curve of overall survival for all patients (n = 76; median 15.3 months).

**Post-study therapies.** One patient with stable disease after six cycles of the study treatment refused maintenance bevacizumab and underwent extrapleural pneumonectomy 1 month after the last chemotherapy/bevacizumab administration; she was censored for progression at the day of last CT scan showing stable disease. Surgery was complicated by bronchopleural fistula with pleural empyema and cardiac herniation, leading to death 1 month after operation.

A second-line therapy was administered to 55 patients (72.4%) progressing after the study treatment. Second-line regimens included gemcitabine, vinorelbine or both in most cases (26 patients), retreatment with an antifolate (pemetrexed or raltitrexed) in 14 cases, and various investigational agents in the remaining 15 patients.

**Serum VEGF levels and treatment outcome.** Pretreatment VEGF serum concentrations were obtained in 39 patients (51.3% of the whole study population). The baseline characteristics of these patients were not significantly different as compared with the general population of the study, except for age that was slightly older. The mean VEGF serum level at baseline was 593 pg ml<sup>-1</sup>, with a very wide range of observations (from 36 to 2079 pg ml<sup>-1</sup>).

In this subgroup of patients, VEGF levels were not related to PFS (Figure 3). A significant correlation with OS was observed when VEGF was analysed as a continuous variable (P = 0.020), but not when VEGF values were categorised according to the median value (P = 0.110) (Figure 4). No correlation was observed between VEGF levels and either response rate or disease control rate.

## DISCUSSION

Based on a strong preclinical rationale and on the survival improvement achieved in other cancers with this treatment strategy, a great hope has been placed in the use of angiogenesis inhibitors in MPM. However, the clinical use of VEGF blockers in MPM patients has resulted more challenging than anticipated. Single-agent trials of tyrosine-kinase inhibitors, administered generally in the second-line setting, have shown disappointing

Table 2. Haematological and non-haematological toxicity by patient (N = 76)

Toxicity	Grade 1 (No.)	Grade 2 (No.)	Grade 3 (No.)	Grade 4 (No.)	Grade 3–4 (%)
<b>Haematological toxicity</b>					
Neutropaenia <sup>a</sup>	3	5	2	4	8
Anaemia	12	20	3	—	4
Thrombocytopenia	2	2	2	—	3
<b>Non-haematological toxicity<sup>b,c</sup></b>

Thrombosis (arterial)	1	1	1	—	1
Bowel perforation	—	—	2	1 <sup>c</sup>	4
Bleeding	14	1	1	—	1

<sup>a</sup>Febrile neutropaenia was reported in two patients.

<sup>b</sup>Other toxicities reported as rare events were grade 2–3 hepatotoxicity (two cases); grade 3 hyperkalaemia (one case) and grade 3 hyperglycemia (one case).

<sup>c</sup>Three toxic deaths were reported: one case for bowel perforation, one case for pneumonitis with a documented H1N1 viral infection, one for a sudden death at home (autopsy not performed).

results (Ceresoli and Zucali, 2012). Maintenance therapy with thalidomide after first-line chemotherapy has failed in improving patient outcome (Baas *et al*, 2011).

As in other neoplasms, bevacizumab has been developed in MPM mainly in the first-line setting, in combination with chemotherapy. Recently, Kindler *et al* (2012) reported the final results of a randomised phase II study of cisplatin/gemcitabine plus

bevacizumab or placebo in patients with advanced MPM. No significant improvement was observed in response rate, PFS or OS with the addition of the angiogenesis inhibitor to chemotherapy. One of the reasons advocated by the authors to explain these disappointing results is a possible negative interaction between bevacizumab and gemcitabine, as shown in preclinical studies (Shaked *et al*, 2008). On the contrary, the combination of bevacizumab and pemetrexed showed therapeutic synergism in a model of orthotopically implanted human MPM cells in immunodeficient mice (Li *et al*, 2007). Unfortunately, these promising preclinical results seem not to be confirmed in the clinical setting. Our multicentre phase II study of pemetrexed and carboplatin plus bevacizumab followed by maintenance bevacizumab failed to achieve its primary end point of a 50% improvement in median PFS in comparison with standard pemetrexed/platinum combinations (Vogelzang *et al*, 2003; Ceresoli *et al*, 2006). The median PFS of 6.9 months was identical to that reported in the above mentioned study by Kindler *et al* (2012) and in another single-arm phase II study of pemetrexed, cisplatin and bevacizumab (Dowell *et al*, 2012; Table 3). As in the other studies with bevacizumab, the median OS observed in our study (15.3 months) was better than that reported in the largest historical series with cisplatin or carboplatin and an antifolate (Vogelzang *et al*, 2003; Van Meerbeeck *et al*, 2005; Ceresoli *et al*, 2006; Castagneto *et al*, 2008). In particular, a higher proportion of 1-year survivor was observed in comparison with our previous study (Ceresoli *et al*, 2006) with pemetrexed and carboplatin alone in the same patient setting (62.6% and 51.6%, respectively). Notably, in the present study 25.9% of patients were alive at 2 years. However, these indirect comparisons must be viewed cautiously, due to different patient selection and designs of the trials, and due to the possible impact of subsequent therapies. Nearly three quarters of patients in our study received second-line treatments at disease progression, and all patients surviving longer than 2 years had a good EORTC score.

In the series reported by Kindler *et al* (2012), pretreatment plasma VEGF levels (obtained in 56 patients over the two treatment arms) were inversely associated with PFS and OS. In an exploratory analysis, a treatment-by-VEGF interaction was suggested; patients in the bevacizumab arm with baseline VEGF levels at or below the median had a significantly better PFS and OS, while in the high VEGF strata there were no significant differences between treatment arms. Our data confirmed the potential prognostic role of VEGF, but no difference in terms of response rate or PFS according to pretreatment serum VEGF levels was observed. Both studies have the important limitation of a small sample size. Several signalling molecules and measures of angiogenesis are under investigations, but validated biomarkers

<sup>a</sup>Double-blind, placebo-controlled trial.

<sup>b</sup>Only patients in the bevacizumab arm were reported.

<sup>c</sup>Included four patients (7.5%) with peritoneal mesothelioma in the bevacizumab arm.

<sup>d</sup>Included eight patients (15%) with mesothelioma of peritoneum and tunica vaginalis.

<sup>e</sup>Assessed at 6 months after starting the treatment.

for predicting response and identifying resistant patients to anti-angiogenic therapies (particularly in MPM) are still lacking (Jain *et al*, 2009; Jubb and Harris, 2010; Carmeliet and Jain, 2011).

Treatment with pemetrexed, carboplatin and bevacizumab was feasible and well tolerated in most patients (Table 2). However, some severe adverse events likely related to bevacizumab, including three toxic deaths (3.9%) and three cases of bowel perforation, were reported. Most serious adverse events occurred during the initial six cycles of therapy, with no significant increase in toxicity during maintenance bevacizumab. The rate of fatal adverse events was in the range of the reported literature (Ranpura *et al*, 2011). Bowel perforation has an average relative risk of 2.14 in cancer patients treated with bevacizumab (Hapani *et al*, 2009), varying with tumour type and drug dose. Interestingly, a higher incidence of visceral perforation was reported in two trials of non-small cell lung cancer patients treated with a regimen similar to that used in our study (Patel *et al*, 2009; Stevenson *et al*, 2012). All these patients had histories of diverticulitis, asymptomatic at enrollment. This was also the case of our patients. No case of visceral perforation was reported in the other trials with bevacizumab in mesothelioma (Jackman *et al*, 2008; Dowell *et al*, 2012; Kindler *et al*, 2012; Zalcman *et al*, 2012). In our trial, however, this adverse event was observed in three elderly patients. Several studies have recently reported a higher risk of developing severe toxicity in older patients who receive bevacizumab with chemotherapy (Ramalingam *et al*, 2008). Although a few surveys have found no significant correlation between the presence of diverticulosis and the risk of bowel perforation with bevacizumab (Saif *et al*, 2007; Abu-Hejleh *et al*, 2012), based on our experience we recommend to exclude at least older patients ( $\geq 75$  years) with a background of colonic diverticulosis from further studies with bevacizumab in MPM.

In conclusion, our study failed to achieve a significant improvement in median PFS, although a longer OS and a higher rate of long survivors were observed in comparison with historical results. However, the study has the obvious limitations of a single-arm phase II trial. Only the results of the ongoing French randomised phase II/III trial evaluating the addition of bevacizumab to pemetrexed/cisplatin (Zalcman *et al*, 2012) will allow to draw definite conclusions about the value of bevacizumab in MPM. Needless to say, a better understanding of the molecular alterations and key pathways that underlie resistance to VEGF-targeting treatments in cancer, with well-designed and adequately powered correlative studies, will help to establish the role, if any, of anti-angiogenic therapy in this lethal disease.
