

EARTHQUAKES, RELIGION, AND TRANSITION TO SELF-GOVERNMENT IN ITALIAN CITIES*

MARIANNA BELLOC
FRANCESCO DRAGO
ROBERTO GALBIATI

This article presents a unique historical experiment to explore the dynamics of institutional change in the Middle Ages. We have assembled a novel data set, where information on political institutions for northern central Italian cities between 1000 and 1300 is matched with detailed information on the earthquakes that occurred in the area and period of interest. Exploiting the panel structure of the data, we document that the occurrence of an earthquake retarded institutional transition from autocratic regimes to self-government (the commune) in cities where the political and the religious leaders were the same person (episcopal see cities), but not in cities where political and religious powers were distinct (non-episcopal see cities). Such differential effect holds for destructive seismic episodes and for events that were felt by the population but did not cause any material damage to persons or objects. Ancillary results show that seismic events provoked a positive and statistically significant differential effect on the construction and further ornamentation of religious buildings between episcopal and non-episcopal see cities. Our findings are consistent with the idea that earthquakes, interpreted in the Middle Ages as manifestation of the will and outrage of God, represented a shock to people's religious beliefs and, as a consequence, enhanced the ability of political-religious leaders to restore social order after a crisis relative to the emerging communal institutions.

*We thank the editor (Robert Barro) and four anonymous referees for comments that greatly have improved the article. We are indebted to Andrei Shleifer for advice and encouragement at many stages of this project. We are grateful to Daron Acemoglu, Alberto Alesina, Zsófia Bárány, Milo Bianchi, Sam Bowles, Tatjana Castano, Eric Chaney, Antonio Ciccone, Pedro Dal Bó, Quoc-Anh Do, Ruben Enikolopov, Oded Galor, Francesco Giavazzi, Pauline Grosjean, Luigi Guiso, David K. Levine, Rachel McCleary, Suresh Naidu, Paolo Nobili, Nathan Nunn, Ben Olken, Ugo Pagano, Elias Papaioannou, Luigi Pascali, Torsten Persson, Maria Petrova, Shanker Satyanath, Fabio Schiantarelli, Annalisa Scognamiglio, Dan Treisman, and to seminar and workshop participants at EIEF, NBER, Paris School of Economics, Santa Fe Institute, York University Toronto, WZB Berlin, Hertie School of Governance, University of Maastricht, Collegio Carlo Alberto, University of Siena, University of Napoli Parthenope, and University of Bologna, and Collegio Carlo Alberto, for useful discussion; to Ivàn Torre, Veronica Dell'Agostino, Mario Luca, Marco Flaccadoro, and Teresa Barbieri for excellent research assistance; to Luca Moiana and researchers at INGV for assistance with the data. Finally, we thank the Departments of Economics at MIT (Belloc) and the Department of Economics at Harvard and the NBER (Drago) for their generous hospitality, and EIEF for financial support. I. INTRODUCTION

Understanding the determinants of institutional change is one of the most important issues in the political economy literature. In particular, empirical investigation of the factors leading to transitions from narrow to broader-based institutions, in the contemporary world and the past, has recently proved of much interest to economists and social scientists alike (Lipset 1959; Barro 1999; Acemoglu and Robinson 2006). One of the main challenges to this literature has been determining how to single out the mechanisms operating in such complicated process and identify the causality. In this article, we contribute by studying how the occurrence of natural catastrophes may impact on the stability of political regimes. We consider an instructive historical case study: the emergence of communes in northern central Italy during the Middle Ages.

Exploiting a panel data set that covers 121 cities over the 1000–1300 period, we find that the occurrence of an earthquake reduces the probability of transition from feudal to communal institutions in cities where political and religious powers were in the hands of the same person, but not in cities where political and religious leaders were distinct. This worked similarly for destructive earthquakes and events that did not provoke any physical damage to people or objects. Our findings are consistent with the view that earthquakes, interpreted in the Middle Ages as manifestations of God's wrath against humanity, reinforced the authority of political leaders who were also religious leaders in the status quo regime.

In the period between the eleventh and thirteenth centuries, Italian cities underwent profound changes in their political and institutional configurations. This is known as the “communal movement,” whereby the power of the incumbent feudal leaders was challenged and often replaced by the bourgeois elite. In the feudal regime, the political leaders were either bishops, in the episcopal see cities, or secular lords (e.g., counts or marquises), in the non-episcopal see cities. In the former group, the bishops were simultaneously political leaders, monopolists in the provision of religious services, and the supreme religious authorities. By contrast, in the non-episcopal cities, religious power was

separated from political power. Bishops and secular leaders ruled free of checks and balances. In the communal system, political power was exercised by representatives of all the citizens and checked by constitutional limitations and representative assemblies. Hence, the transition from the feudal regime to the commune represented a radical change toward broader-based political institutions.¹

Our analysis is conducted on a unique large panel data set. Starting from the sample of the largest cities in northern central Italy for which reliable historical documents on the communal experience are available, we collect information on their political regimes, on whether they were seats of bishops in 1000, and on the year in which the change (if any) from feudal regime to communal institutions occurred. These data are matched with detailed information on the earthquakes (epicenter, locality, time, intensity) that occurred in northern central Italy between 1000 and 1300 (see Stucchi et al. 2007). To impute possible missing seismic episodes due to inaccurate historical sources, we adopt three different augmenting procedures by exploiting the geographical distribution of the cities hit by the earthquakes and the location of the epicenter. We are also able to distinguish between earthquakes for which physical damage to people, objects, and the Earth's surface were reported and those that did not result in material damage but were still felt by the population.

Exploiting the panel structure of the data set and the likely random nature in the timing of the seismic events, we find that unlike non-episcopal see cities, in cities that were seats of a bishop, the occurrence of an earthquake slowed the transition to communal institutions. This negative differential effect is statistically significant and survives several robustness checks. Moreover, the effect of the seismic event on episcopal see cities is confined to the short period: within 10 years after the tremor, it vanishes. Under the assumption that possible differential factors affecting the probability of becoming a commune in the two groups of cities followed a common trend, our finding points to the role played by the bishop in the episcopal see cities and by the

1. It has been amply documented that cities adopting communal institutions reached higher levels of urbanization and rates of growth than those governed by despotic leaders (Coleman 1999; Tabacco 1989; Menant 2005; De Long and Shleifer 1993). Recent work also suggests that communal institutions had a long-term impact on trust and social capital (Guiso, Sapienza, and Zingales 2016).

consequent overlap between religious and political authorities. This explanation is supported by the fact that our results hold for destructive and nondestructive earthquakes. This suggests that the effect of the seismic event on the probability of transition does not depend on the material damage, increase in poverty, deaths, or the (possibly) differential material impact those events had on the social classes involved in the political institutional change.

The interpretation that an earthquake was a shock to religious beliefs and, through this channel, reinforced the status quo regime only where the political leader was also a religious authority is supported by the ancillary evidence that we offer in the last part of the article. Drawing on the data set of the National Office for Ecclesiastical Cultural Assets and Information Services of the Association of Italian Catholic Bishops (CEI, *Conferenza Episcopale Italiana*), we collect an original data set including the dates of construction and further ornamentation of churches and cathedrals by city in northern central Italy in the period of interest. Exploiting this information and relying on the same differences-in-differences design as used before, we obtain that seismic events provoked a positive and statistically significant differential effect on the construction and ornamentation of religious buildings between episcopal see and non-episcopal see cities. Such additional evidence supports the idea that the bishops in the first group of cities were able to take advantage of the occurrence of the frightening events. Our findings can be read in the following framework.

The feudal regime and the commune can be seen as alternative institutional configurations with which to ensure social order (e.g., to minimize the welfare losses due to the expropriation of private property from other citizens; see Djankov et al. 2003), the former relying on the obedience of the citizens to the authoritarian leader, the latter on their participation in public decisions. Before the eleventh century, the feudal society of the collapsing Carolingian empire was characterized by scant civic capital and substantial coordination problems in social and economic relations. In this context, the feudal leader was relatively better able than the civic associations to ensure social order (Cardini and Montesano 2006). From the eleventh century onward, the revival of commerce, the flourishing of economic activity, and

the subsequent increase in per capita income produced incentives for citizens to participate in the management of public affairs, regulate economic transactions, and secure property rights (Greif, Milgrom, and Weingast 1994). The development of devices with which to accommodate the consequent need for enforceable agreements among individuals, such as written contracts, guilds, private associations, and legal rules, enhanced the effectiveness of civic associations in city government and, in some cases, triggered the transition from feudal to communal institutions. This process came about in both episcopal see cities, which in the status quo were ruled by bishops, and non-episcopal ones ruled by secular lords.

One important feature distinguished the secular leader from the bishop: the latter was, besides a political ruler, the head of the local church and the intermediary between the flock of Christians and God (Benvenuti 2010). Hence, his authority was reinforced by the citizens' obedience to norms of conduct and their adherence to religious principles. In the Middle Ages, in Italy and throughout Western Europe, earthquakes were seen as mysterious and unforeseeable events that could only be explained as manifestations of God's wrath. This conviction was widespread, and it was maintained at least until the Enlightenment (Guidoboni and Poirier 2004; Nur and Borgess 2008; Schenk 2010). As amply documented, after an earthquake, people's common reaction was panic, consternation, and an immediate urge for reconciliation with God. This resulted in a sudden increase in attendance at (and thus a greater demand for) religious services, such as collective prayers, processions, and fasts. Consistently with the idea that the Earth's tremor represented a positive shock to religiosity, seismic events were likely to reinforce the religious leaders' authority and thus increase their ability to ensure social order and thus impede transition to communal institutions in episcopal cities. This effect was limited in time, however. Because the process of institutional change induced by improvements in the levels of civic capital, education, and juridical knowledge could not be interrupted indefinitely by an increase in religious beliefs, in the absence of a further shock, the communal movement eventually resumed.

Our study relates to two main strands of the economic literature. The first investigates the role of religion in affecting

political (Barro 1999; Murphy and Shleifer 2004) and economic (Barro and McCleary 2003, 2005; McCleary and Barro 2006; Becker and Woessman 2009) outcomes.² We contribute to this literature by exploring how religion and the correspondence between religious and political leaders account for the probability of institutional change and the stability of political regimes in the medieval period.

The second strand of analysis relevant to our work studies the effects of economic shocks on political support (Healy and Malhotra 2009; Achen and Bartels 2013), institutional change (Brückner and Ciccone 2011; Chaney 2013), and organization into religious communities (Ager and Ciccone 2015).³ The historical experiment described in this article, to the best of our knowledge, provides the first example of how the occurrence of natural catastrophes (through their impact on religious beliefs) may interfere with political and institutional transitions.

The article proceeds as follows. In Section II we outline the historical background. Section III describes the data, and Section IV presents the empirical strategy, the results, and a number of robustness checks. In Section V we report empirical evidence on the relation between seismic events and religious buildings. In Section VI we discuss alternative explanations for our results, finding no compelling and consistent (either historical or empirical) evidence supporting them, and we draw concluding remarks.

2. Barro (1999) studies the relation between a country's primary religious affiliation and its electoral rights indicator, interpreted as a degree of democracy. Murphy and Shleifer (2004) highlight the role of core issues (such as religious beliefs) in building social networks and creating popular support for political leaders. Our results are in line with those of recent research showing that natural disasters increase people's religiosity and church attendance (Penick 1981; Bentzen 2015). On the economics of religion, see, among others, Iannaccone (1991) and Ekelund and Tollison (2011).

3. Healy and Malhotra (2009) show that U.S. voters reward incumbent governments for effective disaster relief spending. Achen and Bartels (2013) find that voters tend to punish incumbent governments for natural disasters. Brückner and Ciccone (2011) offer evidence that negative rainfall shocks are followed by a significant improvement in democratic institutions in contemporary sub-Saharan African countries. Using historical data, Chaney (2013) shows that the probability of change in Egypt's most powerful religious authority decreased during deviant Nile floods. Finally, Ager and Ciccone (2015), considering the nineteenth-century United States, document that counties that faced a greater rainfall risk had a greater share of the population organized into religious communities.

II. HISTORICAL BACKGROUND

II.A. The Status Quo Feudal Regime

At the beginning of the eleventh century, the northern central Italian cities were formally part of the Holy Roman-German empire. They were ruled by either secular lords (non-episcopal see cities) or bishops (episcopal see cities). Until the tenth century the secular rulers (counts or marquises) were directly appointed by the emperor and governed in his name, but in the subsequent period they became increasingly autonomous due to the decline in the political influence of the German emperors' central authority on the fringes of the empire. As a consequence, their power over the city and the territory surrounding the city came to encompass the social, political, judicial, and economic spheres. In addition, the secular feudal lords obtained the establishment of a system of hereditary rule over the territory allocated (Bloch 1961; Ascheri 2009).

Bishops in episcopal see cities performed the same political role as secular feudal lords did in non-episcopal see cities. They acted as officials of the empire, and the emperor granted them the same rights and power wielded by secular rulers. Formally, the city bishops were chosen by the local churches, but the elections were influenced by the emperors. Once elected, they were appointed to local political and judicial offices and governed the city autonomously (Pellegrini 2009). While bishops started to hold political power at least since the late Roman empire (since the Council of Sardica, fourth century CE), their authority was strengthened during the subsequent centuries when, in the absence of a strong imperial rule, bishops were the only recognized local political officers in the cities (Cardini and Montesano 2006). The bishops also held religious power and were the main local authorities in the Catholic Church. They managed—and benefited for life from—the property of the cathedral (the church that was formally the bishop's see), and they could also benefit from the exercise of local fiscal power and rent collection from land and other resources (Tabacco 1987; Ascheri 2009). Unlike secular feudal lords, the bishops did not have the right to transfer their temporal power to their heirs. However, they enjoyed life appointments.

Hence, the bishop was simultaneously the head of the local church and the supreme local political authority (Cardini and Montesano 2006). This fact merits particular emphasis because

(in northern central Italy as in the rest of Western Europe) the Catholic Church was, in its turn, the monopolist of religion. There was no competition with other religious organizations and, in episcopal see cities, the bishop was the head of the hierarchy and controlled the provision of all religious services. In cities with no episcopal see, political power and religious services were more separated: the former was held by secular feudal lords, the latter were provided by several local representatives of the Catholic Church (e.g., parish priests or monks).

II.B. The Emergence of the Commune

During the eleventh century, the northern and central Italian cities experienced an increase in their urbanization rates and economic importance. An urban elite of merchants, entrepreneurs, and lawyers emerged from this background and became economically prominent. Members of this elite soon started to form groups of individuals who agreed, with a *patto giurato* (sworn pact), to provide mutual help and cooperate on issues of common interest (Guiso, Sapienza, and Zingales 2016). Gradually, more stable institutions emerged, and the citizens signatory to the pact began to be involved in the city's government, from which they had been previously excluded. In this period, citizens learned to regulate their economic and social relations and settle their disputes in a decentralized manner, thus reducing the need for a central authority and support to authoritarian leaders.

The shift from the rule of secular feudal lords or bishops to the commune brought a dramatic improvement in terms of citizen participation in the political sphere and the emergence of constitutional checks and balances. The representatives of the commune exercised their power in the name of all the citizens. In particular, the city government was based on a general council of citizens and on elected consules, who held executive power. The general council's decisions were valid only if taken in the presence of a minimum number of citizens, and resolutions were always recorded (Senatore 2008). The consules exercised executive power within the limits of a constitution: the *statutum*. With the commune, personal freedoms were accorded legal protection against abuses by government officials, whose actions were subject to the control of ad hoc institutions, including courts of law to which citizens could appeal (Galizia 1951). Rules, laws, and formal decisions were made

in the name of the citizens (males of majority age owning a house had political rights; women, servants, Jews, and Muslims were excluded). Overall, the commune proved to have some degree of separation of powers, and checks and balances operated similarly as in contemporary democracies.⁴

II.C. Natural Disasters and Religiosity in the Middle Ages

In the Middle Ages, the belief that God was the ultimate cause of natural events was widespread and rooted in the religious doctrine (Le Goff 1982). Important thinkers among the early fathers of the Church supported this view. For example, Philastrius, bishop of Brescia in the fourth century, wrote: "It is a heresy to believe that an earthquake results, not from the will and outrage of God, but from the nature of the elements themselves, thus denying the Holy Scriptures" (Guidoboni and Poirier 2004, p. 130). Isidore of Séville (1960), in his work *De rerum natura*, maintained that God's judgment of sinners (*iudicium peccatores*) was at the origin of earthquakes. Similarly, Thomas Aquinas, whose work represented the synthesis of medieval Christian philosophy, recognized God as the ultimate cause of seismic events (Guidoboni and Poirier 2004). In 1280, Saba Malaspina, a priest serving in Pope Martin IV's curia, described earthquakes as signs of God's wrath (Schenk 2010). Also in the *corpus iuris civilis*, the collection of legal rules written under the Roman emperor Justinian, earthquakes were considered as resulting from sins committed by men against God, such as blasphemy (Schoell 1895).

The Catholic liturgy prescribed specific rituals for protection from natural catastrophes. For instance, during the rogation days (the three days of prayer preceding Ascension Day) people took part in processions and fasts and sang litanies beseeching God to protect them from plagues, natural disasters, and earthquakes. Rogation days were introduced in 463 CE by Mamertus (bishop of Vienne, France) immediately after an earthquake, and they were then extended to the entire Catholic Church by the Council of Orleans in 511 CE (Geary 2010).

4. It is worth noting that when an episcopal see city experienced a shift from the feudal to the communal regime, the bishop lost his political power but maintained his role as religious leader and mediator between God and the people, his religious authority being granted by the Catholic Church hierarchy (Code of Canon Law, Chapter 2, Art.1 Can. 375).

The beliefs that earthquakes were caused by God is reflected in the narrative contemporaries gave of seismic events. For instance, in his report on the history of the city of Milan, Landolfo the Younger (a chronicler who lived at the juncture of the eleventh and the twelfth centuries) described the 1117 earthquake—which, as we shall see, was a crucial episode in the Middle Ages—as an apocalyptic event (Castiglioni 1934). Landolfo wrote that the earthquake was a divine ordeal: people saw drops of blood falling from heaven, a number of miracles and horrific births happened, and thunders could be heard underground and in the water (see also Figliuolo 2010). People were terrified and felt bereft. This description resembles Jesus's representation of the destruction of Jerusalem reported in the Gospel (see, for instance, Matthew 24). Landolfo also reported that, after the earthquake, the bishop and the clergy of Milan organized a ritual in which the whole city participated. For the ceremonials, the archbishop and the representatives of the city set up two stages, one for the bishop and the churchmen and one for the cities' representatives. Citizens crowded around them to attend the burial of vices and revival of virtues.

In the medieval iconography, earthquakes were associated with the Apocalypse (Guidoboni and Boschi 1989) and, in the coeval descriptions, their occurrence was often accompanied by other extraordinary natural events. For instance, the bishop of Cremona, Sicardo, reports that the 1222 earthquake was preceded by a comet (Sicardus Cremonensis 1903); the cleric Pietro Diacono wrote that after the 1117 earthquake a newborn child foretold future prodigious happenings (Hoffmann 1980).

Finally, there is evidence in the coeval chronicles that the occurrence of seismic events was used by the Church to punish wicked people and get rid of its enemies. An exemplary case is provided by the history of Brescia after the 1222 earthquake. The cleric Cesar of Heistenbach associated this seismic episode with the killing of the heretics (Schenk 2010). Indeed, Pope Honorius III exploited the event to justify his violent reaction against these people, whom he blamed for causing the earthquake and whose houses he ordered to be destroyed (Guidoboni and Boschi 1989). The belief that earthquakes were caused by God to punish evil behavior was not limited to Italy—it was widespread in Europe. For example, a chronicle describing the life of Otto, bishop of Bamberg in Germany, reports that in 1117 an earthquake was

provoked by people's sins and the Earth was fighting for God against the "unwise" (Jaffé 1869).

The belief that seismic events were caused by God persisted in Europe at least until the Enlightenment. A turning point came with the earthquake that almost entirely destroyed Lisbon in 1755. Although this event was still seen by some as a manifestation of divine judgment, most thinkers started to reject this idea (Dynes 2000).⁵

II.D. Peoples' Reaction after an Earthquake

In the Middle Ages, the common reaction after an earthquake was panic and consternation. Importantly, nondestructive earthquakes also frightened people. For example, the chronicles report that in 1279 an earthquake with its epicenter in the Umbria-Marche region was felt in Rome only to a small extent. When the earthquake shook, the pope was at dinner. His table and palace moved "miraculously," and the people believed that this heralded God's judgment (Valensise and Guidoboni 2000).

After the immediate panic had subsided, there was an urge for reconciliation and an increase in demand for religious services, particularly processions. Many medieval chronicles refer to a procession as the very first public act in a city after a seismic event, even after episodes that did not cause any physical damage to people or objects (Riera Melis 2010). Their purpose was to purify the city land, and they were conceived as the first step in the restoration of public order. The structure of these rituals, in which all the citizens participated, was designed to demonstrate that the authority of the religious leaders was still strong (Guidoboni and Poirier 2004). For example, in 1222 a violent seismic event hit the city of Modena. The contemporary chronicles reported that the day after the earthquake the bishop led all the clergy and all the citizens of Modena in a procession to purify the city (Dondi 1896). The same happened in 1293 in Pistoia, where the coeval chronicles reported that after an earthquake, which repeatedly struck the city for eight days, all the citizens participated in a number of processions (Adrasto Barbi 1927).

5. The belief that God was the ultimate cause of natural events and the associated rituals prescribed by the Catholic religion can be interpreted in a framework in which superstition is consistent with rational learning (Fudenberg and Levine 2006).

Another religious practice documented by historiography as often taking place after earthquakes and similarly dreadful natural events is the consecration (*dedicatio*). This consists in the religious ceremony with which a building or object is dedicated to God's worship. The ritual has evolved across the centuries and has become one of the most magnificent and solemn ecclesiastical rituals. Given its importance, since the end of the fifth century, the consecration has been conducted by a bishop and has involved a series of religious practices, which last for some days and in which the flock of believers takes part. In the Middle Ages, a church dedication after an earthquake was an important occasion for the people, scared by the manifestation of divine wrath, to please God by offering a religious building or part of it (e.g., an altar) to his worship. At the same time, it was an opportunity for the bishop to demonstrate his power and strengthen his leadership. In Verona, for instance, the church of the Santissima Trinità was dedicated to God's worship on January 12, 1117, just nine days after the seismic event, which was also felt in that city.

After a natural disaster, the bishops had a crucial role in the process of reconciliation with God, not only because they were the monopolists in the provision of religious services in the episcopal see cities, but also because there was a widespread belief that, given their role as intermediaries between God and his flock, the bishops could actually influence natural events. An example is provided by Savino, bishop of Piacenza, who ordered (through his official, a notary) the River Po to stop flooding before it invaded the bishop's lands (Benvenuti 2010).

III. DATA DESCRIPTION

III.A. Sample

Our analysis covers the largest possible number of northern central Italian cities⁶ for which we have been able to verify existence at the beginning of the eleventh century and for which we collected reliable historical sources documenting their institutional (either communal or feudal) form during the 1000–1300

6. Our definition of northern central Italy corresponds to the area of Italy that belonged to the holy Roman-German empire in our period of interest, thus excluding regions that were part of the Norman kingdom (southern Italy) or belonged to other governmental entities (i.e., the city of Aosta, which belonged to the duchy of Burgundy).

period.⁷ The sample consists of two groups of cities, episcopal and non-episcopal see cities, and it is obtained as follows. For the first group, we start from the list of the Italian dioceses (episcopal sees) existing today in northern central Italy as reported in Conferenza Episcopale Italiana (2015), and we examine their history by scrutinizing various sources (e.g., encyclopedic references or the websites of the dioceses). Hence, we verify first which cities existed in 1000 and then whether the chronology of the bishops of each city reports a bishop's name in the year 1000. We include in our first group of cities only those that passed these two filters. It is possible that some cities that were autonomous episcopal sees between 1000 and 1300 lost their status (maybe because they were merged with other dioceses) in subsequent periods, so that they are not reported in the current list of episcopal sees provided by the Conferenza Episcopale Italiana (2015). To minimize the probability of mistakenly excluding these cities from our sample, we also implement the following procedure. Like Guiso, Sapienza, and Zingales (2016), we record the cities on the map *Italia Altomedioevale: Sedi Vescovili* (Treccani 2007), which reports the map of episcopal see cities in the late Middle Ages. Whenever we find a city that is not reported in our previous list, we check in the chronology of bishops whether that city was the see of a bishop in 1000. If so, we include it in our sample.

As for the non-episcopal see cities, we consider the union of the sample of northern central Italian cities offered by Malanima (2005) and that provided by Bairoch, Batou, and Chevre (1998). We carefully study the history of each city in this group by examining a number of sources (e.g., history books, journal papers, encyclopedia entries, or the website of the city). We include in our sample only the cities for which we find evidence that they already existed in 1000. This two-step procedure yields the initial sample of cities for the analysis.

III.B. Transition to Commune

For each city in the sample that we select as just described, we collect information on whether it became a commune during the three centuries considered, and (if so) the year in which the institutional transition occurred. The date of transition is set as

7. This is the period that, according to the historians (e.g., Wickham 1981; Cardini and Montesano 2006), is conventionally identified as relevant for the communal movement.

the first year in which the historical sources offer evidence of the presence of the *consules*, the *statutum*, an official document (e.g., a notarial act) signed by the commune's representatives, or facts identifying the beginning of the communal experience (e.g., imperial charters granting self-government to the city or the description of episodes in which the citizens ejected the feudal leader from the city and established alternative forms of self-government). Because these dates are not systematically available from uniform data sources, we adopt the following criterion. For each city, we consult history books, journal articles, encyclopedia references, and other sources to collect information on the city's communal experience. Whenever we find discordance between sources, we track down another source and opt for a date recorded in at least two of the three sources. If this criterion is not satisfied, we drop the city from the sample. This procedure determines the effective number of cities in our sample: 121, 70 episcopal see cities and 51 non-episcopal see cities. The city names are listed in Table I, where we also report whether the city was the seat of a bishop and, for the cities that became communes in the sample period, the year of transition.⁸

III.C. Earthquakes

The original data on earthquakes are drawn from the DBMI04, assembled by researchers at the Italian National Institute for Geophysics and Volcanology (Stucchi et al. 2007), which contains information on earthquakes occurring in Italian cities between 217 BCE and 2002 CE. The catalog, an extraordinarily rich source of information, is the product of a branch of seismology called historical seismology. This is a multidisciplinary endeavor that uses historical sources to identify the occurrence and effects of seismic events, even in the remote past (Stucchi 1993; Guidoboni 2002). It processes historical information into macroseismic parameters, such as time, epicentral location, and earthquake intensity (Guidoboni and Ebel 2009). The sources of information range from historical records, including archives of public administrations and institutions; diaries, chronicles, and letters; monastic, ecclesiastic, and capitular archives; *notulae* and the archives of notaries; to actual archaeological traces (e.g., damage to churches and buildings and subsequent restorations) left behind by seismic events. In the

8. Detailed sources are reported in Online Appendix B.

TABLE I
SAMPLE AND TRANSITION DATES

| City | Year | Episcopal | City | Year | Episcopal | City | Year | Episcopal |

Notes. The list shows all the cities included in our sample. *Year* is the year when the first evidence of the commune, if any, was found in historical sources. — denotes the city never becoming a commune within the sample period (1000–1300). *Episcopal* denotes whether the city was the seat of a bishop (Yes) or not (No).

past three decades, the meticulous approach adopted by historical seismologists has led to a remarkable improvement in the quality of the investigation, and it has enabled acquisition of information on the effects of earthquakes, often with a surprising amount of detail (Stucchi 1993). The material available through these sources is particularly rich in the case of Italy (Boschi 2000). The historical records for the period studied here refer to universal chronicles, monastic annals, ecclesiastical and liturgical sources, ancient literary sources, and coeval historiography (Guidoboni 2000).

The main source for the geographical references is the ENEL-ISTAT catalog of Italian localities (ENEL 1978) and updates. In the period (1000–1300) and geographical area (northern central Italy) considered in this article, 28 earthquakes occurred; they hit cities included in our sample 102 times (obviously, a city can be struck by more than one seismic episode). They are reported in Table II, which indicates, for each earthquake, the year and the name of the city at the epicenter (or the city nearest to the epicenter).⁹ Column (1) reports the number of cities in our sample, which registered each of the 28 earthquakes. For instance, in 1005, two earthquakes occurred. The first had its epicenter in Arezzo and was registered in two cities included in our sample, Arezzo and Pistoia; hence, the number of cities in the corresponding cell is two (although more than two cities among those not included in our sample were also hit). The second had its epicenter in Cassino and was also registered by two cities, Cassino and Rome, neither of which is included in our sample; this is why the corresponding number of cities in Table II is equal to zero.

The intensity (I) of a seismic event is registered on the Mercalli-Cancani-Sieberg (MCS) scale, which measures the effects brought about by the seismic event on people, natural objects, buildings and other manmade objects, and the Earth's

9. Since the DBMI04 reports the geographical coordinates of the epicenter for each earthquake, we are able to infer the current name of the city closest to it (regardless of whether or not the city existed in 1000). The macroseismic epicenter of a historical earthquake can be identified at the barycenter of the localities where the maximal intensities were registered. The algorithm conventionally adopted for its identification was suggested by Gasperini et al. (1999) and Gasperini and Ferrari (2000).

Notes. The list shows all the earthquakes included in our data. *Epicenter city* is the city closest to the epicenter of the earthquake according to the geographical coordinates provided by the DBMI04. *Year* is the year in which the earthquake occurred. *Registered quakes* are the seismic events registered for our sample cities in the DBMI04. For each of the three augmenting criteria (*polygon*, *epicenter*, *circles*; see later discussion), the number of cities in our sample hit by a seismic event (*All*) and the number of cities hit before transition (*Identifying*) are reported. Note that the numbers of registered earthquakes reported in column (1) may be larger than those in the next columns because the former include all earthquakes with (*D* or *F*) and without (*NR*) registered intensity in the original data set, whereas the latter only include earthquakes for which an intensity could be assigned, as explained in the text with greater detail.

surface.¹⁰ In what follows we distinguish between destructive earthquakes ($I > 5$ on the MCS scale) denoted by D and seismic events that were felt by the population but caused no physical damage ($2 < I \leq 5$) denoted by F . For a number of seismic events, intensity could not be registered in the original data set (DBMI04) because of missing or inaccurate historical sources, these earthquakes are denoted by NR .¹¹

III.D. Augmented Data Set

A possible concern about the data is that not necessarily all the seismic events that occurred in the Middle Ages could be originally recorded because of missing or inaccurate historical sources. Consider an earthquake with its epicenter in city j that occurred at time t . It may be that this earthquake was recorded in the DBMI04 for city j , but not for city i , which was also struck by the seismic episode, because the historical sources for that city were not handed down to the most recent periods. To take this possibility into account, we build an augmented data set according to the three following criteria.¹²

Polygon criterion: For all the cities that in the sample period reported a seismic event with a valid registered intensity (falling in either the D or F category) in the DBMI04, we draw the outer convex polygon and impute an earthquake as occurring in city i at time t if this city was located within the polygon.¹³ Figure I, Panel

10. The scale ranges from 1 to 12: when I stands at 1, this means that people did not feel the earthquake; I at 2 means that the earthquake was felt by very few persons; I from 3 to 5 means that the earthquake was felt by many but did not cause damage; I from 6 to 7 indicates that physical damage was reported; I from 8 to 10 that human victims were also registered; I equal to 11 indicates catastrophic destruction; and I equal to 12 total (apocalyptic) destruction. The strongest earthquake in our sample was registered in Verona in 1117 with I equal to 9.

11. Of the 102 seismic episodes registered in our sample, 48 caused material damage to buildings or persons (D), 25 were felt by people but did not cause any physical damage (F), and 29 were registered with unreported intensity (NR).

12. In our main analysis, we follow a conservative criterion and implement the augmenting procedure exploiting information from those earthquakes which report a valid registered intensity in the DBMI04 (either D or F). We show robustness of our conclusions to this choice by also displaying our results on adopting an extended data set that builds the augmenting procedure (three criteria) on all the earthquakes, those reporting a registered intensity (D or F) and those reporting no intensity (NR) in the original data set.

13. Since the cities are identified by pairs of geographic coordinates that are points on the plane, in order to include cities that might be located on the line between two vertexes of a polygon, we draw the sides of the polygons using buffers

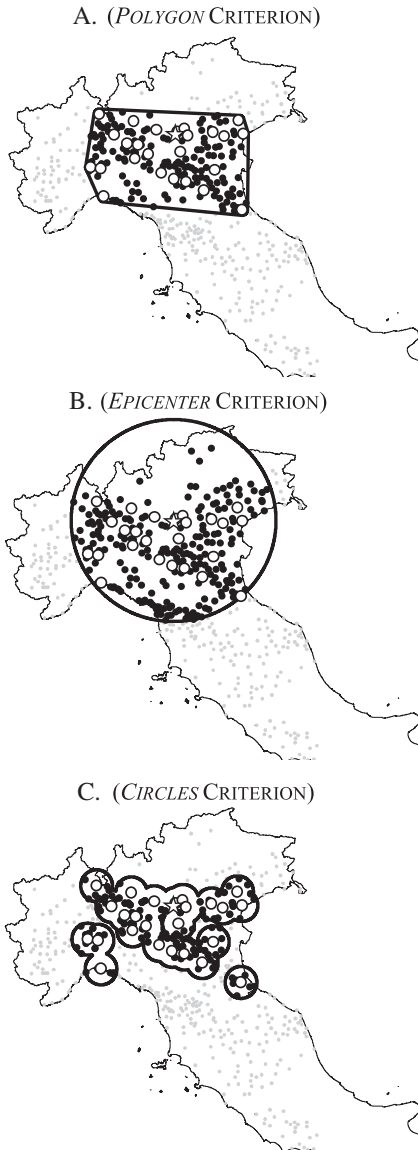

FIGURE I
The Earthquake of 1222

Geographic distribution of the cities hit by the earthquake of 1222. Empty dots represent the cities that reported the earthquake in the DBMI04; full dots denote the cities that were assigned the earthquake by the *polygon*, *epicenter*, or *circles* augmenting criterion, respectively, in Panels A, B, and C. The epicenter is denoted by a star.

A reports an example concerning the earthquake that struck northern Italy in 1222. The empty dots represent the cities hit by the earthquake in the DBMI04. Varese, Treviso, Venezia, Cesena, Genova, and Alessandria represent the vertexes of the outer polygon. The full dots denote the cities that were assigned the earthquake because they were located within the polygon. The epicenter, Lanzise, is denoted by a star. After we augment the data set by means of this criterion, the total number of seismic episodes increases to 274 (of which 151 hit cities before their transition to communes, if any, see Table II).

Epicenter criterion: Consider an earthquake that occurred at time t with its epicenter in city j . Here we draw a circumference with city j at the center and with a radius equal to the distance between city j and the farthest city that reports a seismic event with a registered intensity in the DBMI04. We then assign a seismic episode to all the cities located within the circumference. A graphical representation of this criterion is depicted in Figure I, Panel B, where again the empty dots indicate the cities that registered the episode in the DBMI04, the star denotes the epicenter, and the full dots are the cities imputed by the *epicenter* criterion. The total number of seismic events yielded by this criterion is 443 (of which 259 hit cities before their transition to communes, if any).

Circles criterion: We take all the cities for which the occurrence of an earthquake has been reported in the DBMI04 with a registered intensity and draw an equal number of circles with each of those cities as the center and radius equal to 30 km (we also experiment with alternative threshold distances and obtain no significant differences in the results). We then assign the earthquake to all the cities within the union of these circles. Figure I, Panel C provides an illustration: the empty dots are the registered episodes in the DBMI04 and the full dots are the events created by the *circles* criterion. The total number of episodes identified by this criterion is 201 (of which 99 hit cities before their transition to communes, if any).

For all the seismic episodes included in the augmented data set according to one of these criteria, we also impute intensity and

with widths equal to 20 km. The results described in the following sections do not change in any significant way when alternative widths are used. For earthquakes that hit just one city, we draw a circular area around the city with a radius equal to 20 km. When the earthquake hit two cities, we draw a rectangular area that covers the two cities and whose shortest side is 40 km wide (20 km on each side of the city).

proceed as follows. Consider an earthquake with epicenter in city i ; we draw around city i a circumference with radius equal to the distance between city i and its closest city struck by that earthquake with intensity equal to D . All the cities included in this circumference are assigned intensity equal to D , whereas all the cities that lie outside this circumference but are still assigned an earthquake according to one of the three augmenting criteria report intensity equal to F .¹⁴

Table II shows for each of the three augmenting criteria explained here the total number of cities in our sample hit by an earthquake (columns (2), (4), and (6)) and the number of cities in our sample hit before transition (columns (3), (5), and (7)), which will be used for the identification of the relevant parameters (see later discussion). In some cases we report earthquakes that were not registered in the cities of our sample but were still detected by our augmenting criteria (for instance, the earthquake that originated in Sansepolcro [not included in our sample] in 1270 was not originally registered in our sample of cities but was assigned to Arezzo according to the *circles* criterion). In what follows we refer to the *polygon* criterion as our preferred augmenting methodology.

IV. EMPIRICAL STRATEGY AND RESULTS

IV.A. Identification Strategy

To analyze the effect of an earthquake on the probability of transition to commune, we start by considering the following regression model:

14. With this criterion, we assign F intensity to a larger number of cities than D intensity. For instance, for the *polygon* criterion, we assign F to 200 cities and D to 74 cities. We believe this criterion to be valid for the following reason. On average, the distance from the epicenter for cities that registered destructive seismic episodes is smaller than that for cities that felt only a tremor without reporting any damage. Hence, we assign D to cities inside the circumference and F to those outside it. Since earthquakes do not necessarily spread concentrically, however, in some cases low intensity tremors (that would fall in the F category) in the DBMI04 may be registered closer to the epicenter than destructive episodes. This is why we adopt as a radius of the circumference the minimum distance of a D episode from the epicenter. Note that alternative criteria would not change our conclusions. Finally, the seismic events registered in the original data set—DBMI04—with intensity D or F retain the registered intensity.

$$\begin{aligned}
 \text{transition}_{it} = & \alpha_i + \tau_t + \delta_i \cdot t + \sum_{j=0}^{19} \beta_j \cdot \text{quake}_{it-j} \\
 (1) \quad & + \sum_{j=0}^{19} \gamma_j \cdot \text{bishop}_i \cdot \text{quake}_{it-j} + \varepsilon_{it},
 \end{aligned}$$

where i denotes the city and t indicates the year. The dependent variable, transition_{it} , captures the event of an institutional transition: it is equal to 1 if city i became a commune in year t and 0 otherwise. Since the transition from communal institutions back to the feudal regime was not an option for historical reasons, for a city i that transitioned to a commune in year t , time is not defined after t .¹⁵ This means that the transition to communal institutions is an absorbing state: after becoming a commune, the city drops out of the sample. As a consequence, our data set is an unbalanced panel. Quake_{it} is a dummy variable that is equal to 1 if a seismic event occurred in city i and in year t (according to our augmented data set) and 0 otherwise. Bishop_i is also a dummy variable and equals 1 if city i was the seat of a bishop at time $t = 1000$ and 0 otherwise.

The β -coefficients capture the effect of a seismic event on the transition probability for non-episcopal see cities, whereas the γ -coefficients indicate the differential effect between episcopal and non-episcopal see cities. α_i , τ_t , and $\delta_i \cdot t$ are, respectively, the city fixed effects, the year fixed effects, and the city-specific time trends. Finally, ε_{it} is the error term. We are primarily interested in the γ 's. Under the assumption of common trends, we expect the differential effect between episcopal and non-episcopal see cities to be the result of the overlap between political and religious authorities in the former group of cities. This observation is at the core of our differences-in-differences strategy.

15. In the fourteenth century (hence after the end of our sample period), some cities that had previously established communal institutions adopted an authoritarian form of government ruled by the *signore* (the Lord) and were accordingly named *signoria*. This transition process was highly heterogeneous across cities, and it related to two phenomena: the emergence of a wealthy class of individuals who took control of the city institutions (e.g., the Medicis in Florence) and the territorial expansion of some communes, which conquered the neighboring cities and established regional states. Consequently, since many cities were governed by the same lord (e.g., Bergamo and Cremona were conquered by Milan under the *signoria* of the Visconti family), the number of established *signorie* was remarkably smaller than the number of communes.

In our model specification, city fixed effects take account of the fact that cities may be different in many important permanent unobservable characteristics, which are likely correlated with both the city's seismicity and its probability of an institutional transition (for example, the city's altitude might affect the perception of the Earth's tremor and is also a proxy for the city's strategic position and capacity to repel enemies). Time fixed effects absorb any potential event contemporaneous with the earthquake for all the cities (e.g., a famine) that may affect the probability of a transition. Time fixed effects ensure that identification is obtained conditional on shocks common to cities with and without earthquakes in each year. Finally, the city-specific time trends account for possible slow-moving social and cultural variables (e.g., civic and human capital accumulation) specific to each city in the sample and which are correlated with both a city's probability of becoming a commune and its probability of registering an earthquake. In fact, in our data, both probabilities are positive functions of time (see Tables I and II). Importantly, these trends may vary from city to city because, for instance, cities experiencing increases in education and civic capital accumulation steadily enhance their ability to register earthquakes. The omission of one or both sets of fixed effects or of the city-specific trends would lead to a potential bias in the coefficients of interest. Their inclusion allows us to exploit the random nature of the timing of the seismic episodes that is the central feature of our design.

We explore the dynamic treatment effects by including lagged earthquake variables because we are interested in not only the contemporaneous effect but also its duration.¹⁶ We consider lagged quake variables up to 20 years because we expect our effect of interest to develop in a relatively short period. As we will show, this expectation is confirmed by the data.

Given the large number of fixed effects included, model (1) and its modifications are estimated adopting a linear probability model (LPM). The limitations of this approach and alternative functional forms are discussed in Section IV.F. To take account

16. Moreover, if the effect of a seismic event on the transition probability lasts for a few years after its occurrence, by omitting the lagged earthquake variable, we would mistakenly include in the control group observations treated by the seismic event. The estimated coefficient of the contemporaneous effect would be biased as a consequence.

of potential spatial correlation of the error terms in an unknown form, we employ Conley's method (Conley 1999) to compute the standard errors, in which the spatial dependence between two observations in two different cities decreases with the distance between the cities. This method requires a threshold distance after which the dependence disappears. Our preferred threshold is 100 km, meaning that error spatial dependence decreases linearly between 0 and 100 km and disappears for longer distances. This is justified by the fact that, for earthquakes registered by multiple cities in the original data set, the average distance between the epicenter and the farthest city with a registered intensity is about 100 km. In our analysis, we present standard errors clustered at the city level and Conley's standard errors obtained with alternative threshold distances (200 km or 500 km).

IV.B. Diagnostic Tests and Preliminary Evidence

The three criteria described in Section III.D (*polygon*, *epicenter*, and *circles*) assign possibly missing seismic events to cities by starting from *recorded* earthquakes (respectively, the vertexes of the polygons, the epicenter, the center of the circles). Hence, our augmenting procedures necessarily cannot take into account earthquakes that were registered in no city according to the DBMI04 because the relative documents were not handed down to the historical sources. This may be important in the presence of pretrends. For instance, if transitions in episcopal cities, unlike in non-episcopal ones, happen during a period of political turmoil or in the presence of other circumstances that negatively influence the probability of registering an earthquake, we would erroneously attribute to a seismic episode a negative impact on the probability of becoming commune, when no true differential effect exists. This, in turn, would imply a negative differential effect of the seismic event between the two groups of cities. If these circumstances last for some years after the transition, we would also observe negative differential effects of the leads of the earthquake variable on the transition. Thus, finding no negative differential effects of the earthquake on past transitions is consistent with the absence of pretrends.

To verify the presence of possible pretrends and provide preliminary evidence on the differential effects of earthquakes on the transition probability, we estimate model (1) including both lags and leads in the earthquake variable. Since the outcome is an

Leads and Lags (β and γ)

Estimated β - and γ -coefficients by OLS of model (1) with 20 leads and lags. Year fixed effects, city fixed effects, and city time trends always included. The dependent variable, *transition*, is = 1 if city i became a commune at time t and = 0 otherwise. The independent variable, *quake*, is = 1 if an earthquake occurred in city i at time t and = 0 otherwise. The confidence intervals are computed employing Conley's standard errors corrected for spatial dependence with threshold distance of 100 km.

absorbing state, lead and lag effects must be estimated separately. In estimating the coefficients on the leads, we leave the outcome variable equal to 1 if a transition occurred in city i and at time t and set it equal to 0 in the following periods (before t , time is not defined and the city drops).

The results are shown in Figure II, where, for each augmenting criterion, we plot the estimated β - and γ -coefficients from model (1) and the associated confidence intervals according to the estimated Conley's standard errors with 100 km threshold distance. On the left, we report coefficients on the leads as they capture a relation between the occurrence of an earthquake in a given period and past transitions. On the right, we measure the contemporaneous coefficient and coefficients on the lags, reflecting the dynamic treatment effects, as they reveal a relation between an earthquake at time t and future values in the outcome variable.

Three empirical patterns are apparent in Figure II. First, although the estimated β -coefficients are close to 0, most of the point estimates of the lagged differential effects between episcopal and non-episcopal see cities, the γ -coefficients, are negative, especially in the very short run. These results suggest that the occurrence of an earthquake slows the transition to communal institutions only for episcopal see cities. The effect appears to last longer when we consider the *circles* augmenting criterion (Figure II, Panel C) and to last for a shorter time when we adopt the other two criteria, *polygon* and *epicenter* (respectively, Figure II, Panels A and B).¹⁷ Second, no negative pretrend appears from the plotted lead effects. If anything, the effects are virtually zero with point estimates slightly above zero. Third, the large confidence intervals associated with a number of coefficients suggest that they are quite imprecisely estimated. It is likely that exploiting the annual variability in the earthquake variable generates noise in the estimation. In fact, the latter finding advises us to adopt a model that aggregates the effects of the

17. To convey the dynamics better, in the Online Appendix A (Figures A.1) we also report the coefficients on the contemporaneous *quake* variable and its lags up to 40 years. For all the three augmenting criteria, the differential effect of an earthquake is mainly confined to the two decades following the seismic event, being precisely estimated especially in the first five years of the first decade. Starting from the third decade, the effect vanishes and most of the coefficients turn out to be not statistically different from zero. This exercise confirms that the effect of the earthquake is confined to the short run.

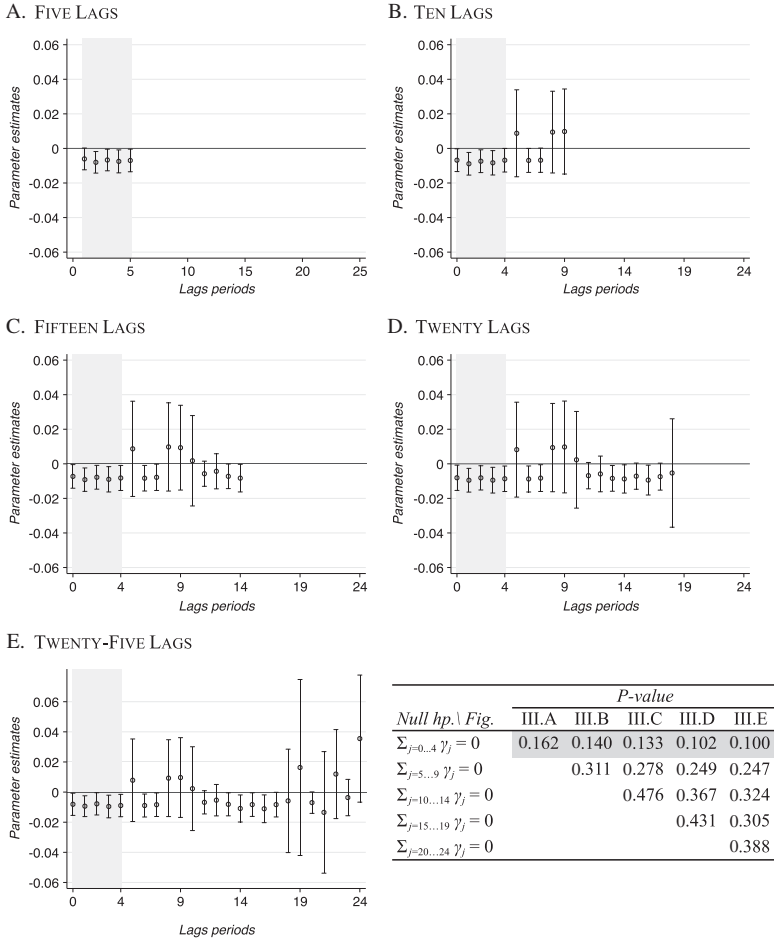

FIGURE III

Lag Structure (*Polygon Criterion*): Differential Effect (γ)

Estimated γ -coefficients by OLS of model (1) with a variable number of lags. Year fixed effects, city fixed effects, and city time trends always included. The dependent variable, *transition*, is = 1 if city *i* became a commune at time *t* and = 0 otherwise. The independent variable, *quake*, is = 1 if an earthquake occurred in city *i* at time *t* and = 0 otherwise. The confidence intervals are computed employing Conley's standard errors corrected for spatial dependence with threshold distance of 100 km.

earthquakes across consecutive years that we report in the following sections.

In Figure III, we show the estimated γ -coefficients from model (1) modified to include up to 25 lagged earthquake dummies (for the *polygon* criterion only, for reasons of space). The p -values computed from a test of joint significance of the lagged differential effects grouped by five-year periods are also reported. They suggest that the differential effect of an earthquake in the first five years following the event is robust to the inclusion of an increasing number of lags. Moreover, as one can see, the effect of an earthquake lasts at most 20 years (i.e., the lagged effects between 20 and 25 years are practically insignificant) and adding a number of lags larger than 20 does not substantially contribute to improving the estimation precision for the coefficients on the previous lags. Consequently, we perform the empirical analysis including lags up to 20 years.

IV.C. Aggregate Effects and Intensity

For reasons of tractability and to gain in efficiency, we give more structure to the model and aggregate the effects of earthquakes on the transition probability in five-year effects. We thus estimate the following regression equation:

$$(2) \quad \begin{aligned} \text{transition}_{it} = & \alpha_i + \tau_t + \delta_i \cdot t + \sum_{h=0}^3 \beta_{-5h} \cdot \text{quake}_{-5h,it} \\ & + \sum_{h=0}^3 \gamma_{-5h} \cdot \text{bishop}_i \cdot \text{quake}_{-5h,it} + \varepsilon_{it}, \end{aligned}$$

where $\text{quake}_{0,it}$, $\text{quake}_{-5,it}$, $\text{quake}_{-10,it}$, and $\text{quake}_{-15,it}$ are equal to 1, respectively, in the first, second, third, and fourth five-year interval following the earthquake, and 0 otherwise (note that although data are annual, the effects are aggregated every five years).

The estimated coefficients in this model represent the average effect of an earthquake over each five-year period. Columns (1)-(2)-(3) of Table III show our main results from regression (2) on adopting, respectively, the *polygon*, the *epicenter*, and the *circles* criterion. For each augmenting criterion, we report the estimated β - and γ -coefficients. Conley's standard errors corrected for

Notes. Estimation by OLS of model (2). Year fixed effects, city fixed effects, and city time trends always included. Number of observations = 23,972; number of cities = 121. The dependent variable, *transition*, is = 1 if city *i* became a commune at time *t* and = 0 otherwise. The independent variable, *quake*, is = 1 if an earthquake occurred in city *i* at time *t* and = 0 otherwise. Columns (1)-(3) refer to the data set augmented by exploiting only information from the earthquakes which report a valid intensity in the DBM104; columns (4)-(6) refer to the data set augmented by also employing the seismic events for which intensity was not registered in the DBM104; columns (7)-(9) refer to the data set that only considers destructive earthquakes with intensity between 6 and 10 (physical damage to people or objects). The subscripts 0, -5, -10, -15 refer to the five-year lag respectively: from *t* to *t*-4, from *t*-5 to *t*-9, from *t*-10 to *t*-14, and from *t*-15 to *t*-19). Conley's standard errors corrected for spatial dependence with threshold distance of 100km are reported in parentheses; standard errors clustered at the city level are in square brackets. *** = significant at 1%; ** = significant at 5%; * = significant at 10%. Statistical significance is indicated employing the Conley's standard errors.

spatial dependence with thresholds distance of 100 km and standard errors clustered at the city level are reported in round and square brackets, respectively. Statistical significance is indicated employing Conley's standard errors, which in most cases are very similar to clustered standard errors.

Our results suggest that the occurrence of an earthquake has always a negative and statistically significant differential effect between episcopal and non-episcopal see cities in the first five years following the event. In particular, within the five years after the earthquake, the difference in the change of the probability of transition between the two groups of cities (γ_0 in column (1)) is equal to -0.85 percentage point when we consider our preferred augmenting criterion (*polygon*). Taking into account the corresponding estimated β -coefficient, these estimates imply that an earthquake pushes the probability of transition to 0 for episcopal see cities. Similar conclusions are drawn when we consider the *epicenter* and the *circles* criteria (columns (2) and (3)).

Columns (4)-(5)-(6) of Table III report our regression output on employing an extended data set that also exploits information from earthquakes with unreported intensity in the augmenting procedure described in Section III.D (respectively for the three criteria, *polygon*, *epicenter*, and *circles*). Our conclusions are not altered in any relevant way. In columns (7)-(8)-(9), we show corresponding results obtained on a more restrictive data set that only comprises destructive earthquakes, i.e. seismic episodes with intensity in MCS scale greater than 5 (intensity class *D*). Again results are consistent with those presented in columns (1)-(2)-(3), but suggest a somewhat larger effect.

Finally, we employ a similar modeling strategy to exploit information on the intensity of seismic events. Here we distinguish between earthquakes that were only felt by the population but did not cause any damage (with intensity in MCS scale greater than 2 and smaller than or equal to 5; *F*), denoted by $fquake_{it}$, and destructive earthquakes (with intensity greater than 5; *D*), denoted by $dquake_{it}$, and estimate the following model:

Notes. Estimation by OLS of model (3). Year fixed effects, city fixed effects, and city time trends always included. Number of observations = 23,972; number of cities = 121. The dependent variable, *Transition*, is = 1 if city *i* became a commune at time *t* and = 0 otherwise. The independent variable, *quake*, is = 1 if an earthquake occurred in city *i* at time *t* and = 0 otherwise. Columns (1)-(4)-(7) report the effects of destructive earthquakes with intensity between 6 and 10 (physical damage to people or objects), columns (2)-(5)-(8) report the effects of seismic events with intensity between 2 and 5 (no physical damage). The subscripts 0, -5, -10, -15 refer to the five-year lag respectively: from *t* to *t* - 4, from *t* - 5 to *t* - 9, from *t* - 10 to *t* - 14, from *t* - 15 to *t* - 19). Conley's standard errors corrected for spatial dependence with threshold distance of 100 km are reported in round brackets; standard errors clustered at the city level are in square brackets. ** = significant at 1%; * = significant at 5%; * = significant at 10%. Statistical significance is indicated employing the Conley's standard errors. Columns (3)-(6)-(9) report the *F*-test that $\gamma^A = \gamma^B$ (null hp) computed employing Conley's (clustered) standard errors in round (square) brackets.

$$\begin{aligned}
 \text{transition}_{it} = & \alpha_i + \tau_t + \delta_i \cdot t + \sum_{h=0}^3 \beta_{-5h}^D \cdot \text{dquake}_{-5h,it} + \sum_{h=0}^3 \beta_{-5h}^F \cdot \text{fquake}_{-5h,it} \\
 & + \sum_{h=0}^3 \gamma_{-5h}^D \cdot \text{bishop}_i \cdot \text{dquake}_{-5h,it} + \sum_{h=0}^3 \gamma_{-5h}^F \cdot \text{bishop}_i \cdot \text{fquake}_{-5h,it} + \varepsilon_{it}.
 \end{aligned}
 \tag{3}$$

The results are shown in Table IV. Specifically, columns (1), (4), and (7) report for the three criteria the effect of an earthquake with D intensity in non-episcopal see cities (β^D) and the differential effect between episcopal and non-episcopal see cities (γ^D). The corresponding coefficients for seismic events with F intensity (β^F and γ^F) are shown in columns (2), (5), and (8). In columns (3), (6), and (9), we list the results of an F -test of equality of the γ -coefficients on destructive and nondestructive earthquakes. We find that both D and F seismic events always have a negative differential effect on the transition probability in the first five years after the earthquake. The point estimate for a seismic event with intensity D is larger, in absolute value, than that associated with intensity F ; however, when we use Conley's standard errors, the F -test never rejects the null hypothesis that the two coefficients are equal. Overall, the results in Table IV suggest that we cannot exclude that earthquakes only felt by the population with no physical damage to people or objects also slowed the establishment of communal institutions in episcopal see cities.

IV.D. Placebo Test

To check the robustness of our results, we implement a placebo test in the spirit of Chetty, Looney, and Kroft (2009) adopting our preferred augmenting criterion (*polygon*). In our sample of years and cities, 28 earthquakes took place in northern central Italy, which (according to the *polygon* criterion) generated 274 city-episodes (the total number of seismic events reported in Table II). We then produce 28 "placebo" earthquakes occurring in 28 random years and assign them to random cities for a total of 274 events. Although randomly assigned, the placebo earthquakes reflect the true time and space clustering of the real data. The time clustering is obtained every 50 years: for instance, we generate six placebo earthquakes between 1150 and 1200, which mimic, in random cities and years, the earthquakes that really occurred in 1168 (three cities), 1170 (one city), 1182 (one

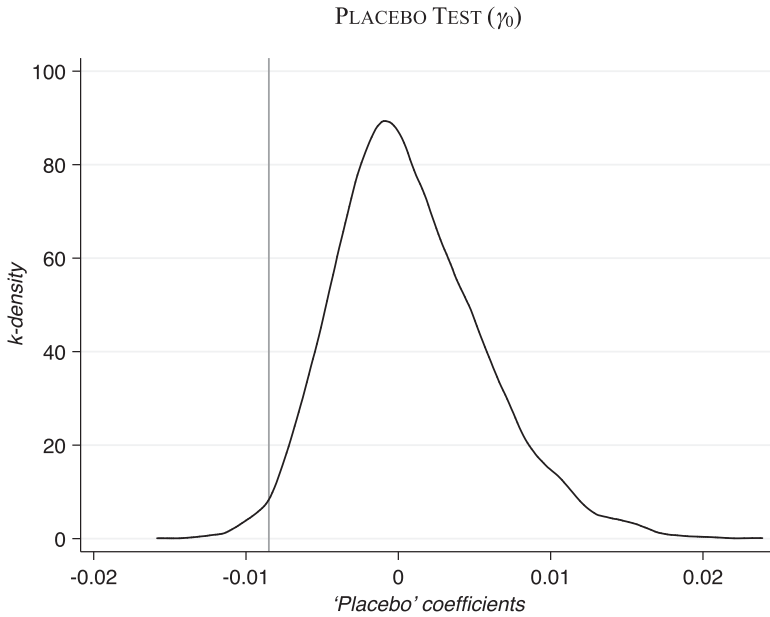

FIGURE IV
Placebo Test (γ_0)

Probability density function of the differential coefficients on the first five years following a seismic event (γ_0) obtained by estimating regression (2) with the placebo earthquake dummy as independent variable, as explained in Section IV.D, and iterating 10,000 times. The vertical line indicates our true point estimate (-0.0085), which is reported in column (1) of Table III (*polygon* criterion).

city), 1194 (seven cities), 1196 (two cities), and 1197 (one city). The space clustering is produced within circular areas around the real epicenter with radius equal to 100 km. For instance, to mimic the earthquake that originated in Arezzo in 1005, we generate a placebo earthquake that is assigned in a random year between 1000 and 1050 to six random cities located within 100 km distance from Arezzo; those cities must be different from the six cities that were really hit by this earthquake in 1005 according to the *polygon* criterion.¹⁸ Hence, we build the placebo earthquake dummy variable and estimate model (2) including it in the place of the

18. The space clustering is not imposed when we mimic the earthquakes that occurred in 1117 and 1222 because they covered very large areas.

real one. We repeat this procedure 10,000 times (employing alternative numbers of replications do not affect our results in any significant way) and save the estimated coefficients. The results, presented in Figure IV, show the probability density function of the 10,000 placebo point estimates of the γ_0 -coefficient, a vertical line indicating our true point estimate for the differential effect in the first five years after an earthquake (equal to -0.0085 , reported in column (1) of Table III).

The purpose of this test is to check how many times these randomly generated placebo point estimates happen to be smaller or too close to our true point estimate. If in our main results we were erroneously rejecting the null hypothesis that our coefficient of interest is equal to 0 (i.e., we were attributing to earthquakes a negative effect that does not exist in reality), we should have observed placebo coefficients very close to our true estimate. As can be seen from Figure IV, the point estimates generated in the falsification test are almost always to the right of (meaning larger in value than) the true estimated coefficients. This does not obtain in only 1.23% of cases: moreover, in the 0.92% (0.4%) of cases the fake estimated coefficient is larger than the true one and statistically significant at the 5% (1%) level.¹⁹ Overall this exercise offers considerable evidence that our results are not an artifact of a small number of treated cities in the data set and the potentially correlated nature of the error terms.

IV.E. Further Analysis and Robustness Checks

As is clear from Table II, a large fraction of the seismic events considered in our exercise are generated by the earthquake that struck northern-central Italy in 1117. In order to investigate how this or other particular episodes contribute to generating our previous results, we re-estimate model (2) by isolating the effect of each single earthquake (captured by a dummy variable that equals 1 if earthquake x struck city i at time t , and 0 otherwise) from the effect of all the other seismic events (captured by a dummy variable that equals 1 if an earthquake different from x struck city i at time t , and 0 otherwise). Adopting our preferred imputation criterion, we perform 20 different regressions (20 is the number of events that, according to the *polygon* criterion, hit at least one city before transition to a commune, if any: this

19. On employing the other two augmenting criteria, *epicenter* and *circles*, the conclusions do not change in any relevant way.

Notes: Estimation by OLS of the γ_0 -coefficient in model (2) obtained on dropping earthquakes one-by-one and on adopting the *polygon* criterion. Year fixed effects, city fixed effects, and city time trends always included. Number of observations = 23,972; number of cities = 121. The dependent variable, *transit*, is =1 if city *i* became a commune at time *t* and =0 otherwise. The main independent variable, *quake*, is =1 if an earthquake (excluding *x*) occurred in city *i* at time *t* and =0 otherwise. Panel A refers to the dataset augmented exploiting only information from the earthquakes which report a valid intensity in the DBMI04; Panel B refers to the dataset augmented also employing the seismic events for which intensity was not registered in the DBMI04. Conley's standard errors corrected for spatial dependence with threshold distance of 100 km are reported in round brackets; standard errors clustered at the city level are in square brackets. *** = significant at 1%; ** = significant at 5%; * = significant at 10%. Statistical significance is indicated employing the Conley' standard errors.

corresponds to the number of non-zero cells in column (3) of Table II). In Table V, we report our coefficients of interest, namely the differential effects of earthquakes (excluding x) on the transition probability of Episcopal see cities in the first five years. Panel A displays results obtained on adopting the data set that only exploits information from earthquakes with a registered intensity in the DBMI04. The estimated γ_0 -coefficients are always negative and vary across regressions in most of the cases, suggesting that all the earthquakes contribute to estimating the effect under study, though admittedly these changes are small. When we exclude the earthquake which struck northern-central Italy in 1117 (this earthquake hit 92 out of 121 cities), the point estimate on the *quake* variable in the first five-year interval for the Episcopal cities remains negative (-0.0028 with a t -statistics equal to -1.41), indicating that, while the 1117 earthquake is a strong driver of our results, it is not the only episode that generates the regression output.²⁰ Panel B shows our results when we employ the data set constructed by also exploiting information from earthquakes with unreported intensity (*NR*) in the DBMI04. The estimated γ_0 -coefficients are always negative and turn out statistically significant at least at the 10% level. To show how sensitive our estimated standard errors are to the thresholds of 100 km employed in Conley's correction, we compute the spatially corrected standard errors obtained on adopting thresholds of 200 and 500 km (estimation output is shown in Online Appendix Tables A.1 and A.2 for models (2) and (3), respectively); the results are substantially the same as before. Finally, we investigate whether our findings are robust after we drop cities one-by-one (this set of 121 regressions is available upon request). No compelling evidence suggests that the results change on the exclusion of some cities in any significant way.

20. The fact that, after washing out the effect of the earthquake that occurred in 1117, our estimated γ_0 -coefficient becomes smaller in absolute value and turns out marginally significant is unsurprising. Since the 1117 quake generates a large fraction of the seismic events used for identification in our analysis, its dismissal reduces power in estimation. This is confirmed by the fact that, as shown in the bottom panel of Table V, when we employ the extended data set built on all the seismic events (with and without a registered intensity), the relevant coefficients are always (negative and) statistically significant.

IV.F. *Alternative Functional Forms*

One potential concern with using a LPM is that this estimation method could provide an imprecise approximation of the marginal effects, especially when there is a mass of zeroes in the dependent variable, as in our design.²¹ Alternative functional forms are the conditional logit model and duration analysis. We consider them in turn.

A conditional logic model in our case suffers from two substantial limitations. First, this method leads us to discard all the information from cities that never transitioned to communes and does not reach convergence when year fixed effects and city-specific time trends are included.²² Second, differential effects in nonlinear models, such as the conditional logit, are difficult to interpret (Ai and Norton 2003). Nonetheless, a logic model conditional on city fixed effects allows estimation of the parameters of interest and may prove useful for verifying whether the implied negative and statistically significant effect of earthquakes on the transition probability for episcopal cities is confirmed in a nonlinear model. In fact, reassuringly, the conditional logit model yields results qualitatively similar to those provided by the LPM for episcopal see cities (results are in Table A.3 of Online Appendix A).

A duration model would not be appropriate in our context either. Indeed, a Cox model with no time-varying covariates would ignore the panel structure of the data, whereas a Cox model with time-varying covariates (i.e., the earthquakes) could not accommodate time fixed effects, city-specific time trends, and city fixed effects (which are important in our analysis to exploit the plausible randomness in the occurrence of the seismic events,

21. Alternative models, such as logit or probit, present serious limitations in our design. In particular, the inclusion of (city or year) fixed effects would be problematic. First, a large set of fixed effects (as in our case) would yield inconsistent slope estimates due to the incidental parameter problem (Wooldridge 2002); second, including city and year fixed effects would lead to the loss of all the information related to cities that were hit by earthquakes but never experienced a transition and years in which we do not observe a transition. More generally, all the observations for which the independent variable perfectly predicts the transition outcome would be dropped from the analysis (see Zorn 2005).

22. These limitations are not minor. Cities that never transitioned to communes contribute to the identification of our effect of interest as long as they are hit by an earthquake. Year fixed effects and city-specific time trends are also important in our design, as explained in Section IV.A. The problem of convergence with a large set of fixed effects is common in maximum likelihood estimations (Greene 2004).

as explained in Section IV.A). Moreover, the Cox model incurs the same estimation problems as a standard logit whenever the independent variable perfectly predicts the outcomes (see note 21). This makes estimation of the dynamics of the effects of earthquakes not feasible when the outcome variable (*transition*) is always equal to 0 in correspondence to the earthquake variable, or its lags, equal to 1. Finally, a duration model (with or without time varying covariates) would make it difficult to distinguish between short- and long-run effects of (possibly multiple) earthquakes on the transition probability. To conclude, the LPM seems the most appropriate model in our design to exploit the random nature of the timing of earthquakes. This is especially the case when considering the more serious limitations of alternative models (conditional logit or Cox model).

V. EARTHQUAKES AND RELIGIOUS BUILDINGS

V.A. *Anecdotal Evidence*

Our interpretation of the previous results holds under the assumption, supported by the narrative historical evidence in Section II, that an earthquake represented a shock to people's religiosity and the bishop was able to take advantage of it in terms of his political and religious power. Providing empirical test of this hypothesis is no simple exercise, given the absence of systematic data in the medieval period and the impediments to appraising religious beliefs directly. Yet an indirect measure of the intensity of the religious feelings in a given city in a certain period could be given by the number of constructions and ornamentations of religious buildings. Indeed, according to the Catholic doctrine, churches and cathedrals are not only the houses of God where people celebrate rituals, they are also important manifestations of people's faith in God.

Medieval history furnishes several cases in which people reacted to the dread and consternation caused by a seismic event with an increase in votive offerings and enrichments of religious buildings. These were powerful means to please God and to seek reconciliation after a crisis. One example is provided by the history of Bergamo. The year 1117 was crucial for the monastery of Santo Sepolcro in Astino (located near the city of Bergamo): immediately after the earthquake that shook northern central Italy, substantial offerings were given by two consuls (officials) of

Bergamo to the monks of Astino. As testified in a document written in January 1117, the offerings were made in the name and on request of the citizens (“*per parabolam et consensum fere omnium civium Pergamensium*”) for the salvation of their souls (“*pro remedio animarum nostrarum et omnium vicinourm masculini et feminini sexus*”) (Bartoli Langeli 2015). Besides saving the citizens’ souls, it turned out that the offerings represented building blocks for the economic, religious, and political enhancement of the monastery and constituted an official and definitive endorsement of its political and religious influence over the surrounding region.

Further examples are suggested by the history of Verona. In that city, after 1117, the bishop Bernardo promoted the reconstruction of several ecclesiastic buildings in the city. This undertaking has been scrutinized by historians and archeologists because of its importance for the city’s urban structure (Codén 2010). The bishop was able to take advantage of the earthquake not only by investing resources in the construction and ornamentation of the ecclesiastic buildings of Verona but also by enlarging the size of the ecclesiastic properties under his direct control. In 1122 he transformed the Benedictine monastery of San Giorgio—which, like any monastery, was independent from the episcopal authority—into an *ecclesia* by replacing the abbot (the head of the monastery elected by the monks) with a *prepositus* nominated by the bishop himself (Passuello 2014). Finally, an anecdote reported by Guidoboni and Poirier (2004) illuminates the effects of earthquakes on citizens’ deference to the Church. In Verona, a nobleman named Rodolfo used to exact (sometimes with the use of violence) payment of a tithe by the priest of a local church. Immediately after the tremor that hit Verona in 1117, Rodolfo was so scared for his life and soul that decided to renounce the tithe (Guidoboni and Poirier 2004; Galli 2005).

In light of the historical episodes, in the remainder of this section we offer econometric evidence that, in our sample of cities and years, the occurrence of a seismic event has a positive differential effect between episcopal see and non-episcopal see cities in the construction of religious buildings and the maintenance of their magnificence. All other factors equal, this differential effect between the two groups of cities is likely to be the consequence of the bishop’s ability to exploit his religious and political role and take advantage from the occurrence of an earthquake to boost the citizens’ religiosity and deference to the Church.

V.B. Data Description

To run the exercise, we assemble an original data set on religious buildings' construction and related ornamentation in the 1000–1300 period. We start by considering the data collected by the National Office for Ecclesiastical Cultural Assets and Information Services of the Association of Italian Catholic bishops (CEI, Conferenza Episcopale Italiana), which lists for all the Italian cities the existing churches and, for a number of them, registers the year in which the church was built and possibly renovated. In regard to northern central Italy and the historical period under analysis, after uncertain dates of construction are discarded, this information is available for 194 events (146 in episcopal see cities and 48 in non-episcopal see cities). Since the CEI project is still ongoing and proceeds at different speeds for different dioceses and different cities, these data may be incomplete. Consequently, we augment the original database and proceed as follows. Starting from the list of churches provided by CEI, in the case of those for which the date of construction or further ornamentation was not reported, we obtain this information (whenever possible) from history books, journal articles, encyclopedia references, and other sources.²³ This effort enables us to augment the CEI data set to including 663 additional church events (545 and 118 episcopal see and non-episcopal see cities, respectively). However, it might happen that a given city was reported as having no church by the CEI database because of slow registration or data collection by the local ecclesiastic administration. Hence, our analysis considers only the subsample of cities that, according to CEI, have at least one church. These cities number 97 (out of 121): 61 episcopal see cities and 36 non-episcopal see cities. Finally, for episcopal see cities, we also collect data on the history of each cathedral from historical books and encyclopedias and annotate its year of construction and further ornamentation (if any). Considering cathedrals, our extended data set includes information on 681 events (563 and 118, respectively in the two groups of cities). Hence, we have three data sets of interest: the CEI data set, the extended data set (CEI and additional sources) that comprises only

23. Detailed sources are reported in Online Appendix C.

Notes: Estimation by OLS of model (4). Year fixed effects, city fixed effects, and city time trends always included. Number of observations = 17,852; number of cities = 97. The dependent variable, *religious buildings*, is =1 if in city *i* at time *t* a *religious building* event occurred (construction or renovation) and =0 otherwise. The independent variable, *quake*, is =1 if an earthquake occurred in city *i* at time *t* and =0 otherwise. Columns (1)-(3) refer to the CEI data set for churches; columns (4)-(6) refer to the extended data set that includes information from CEI and further sources for churches only; columns (7)-(9) refer to the extended data set that also includes information for churches and cathedrals. The subscripts 0, -5, -10, -15 refer to the five-year lag (respectively; from *t* - 4, from *t* - 5 to *t* - 9, from *t* - 10 to *t* - 14, from *t* - 15 to *t* - 19). Conley's standard errors corrected for spatial dependence with threshold distance of 100 km are reported in round brackets; standard errors clustered at the city level are in square brackets. *** = significant at 1%; ** = significant at 5%; * = significant at 10%. Statistical significance is indicated employing the Conley's standard errors.

churches, and the extended data set (CEI and additional sources) that includes both churches and cathedrals.²⁴

V.C. Estimation and Results

To minimize noise in the annual data and provide evidence consistent with the main empirical patterns presented in previous sections, we adopt the aggregated version of our model (model (2); results reported in Table III). The model estimated differs only in the dependent variable, here capturing the religious building constructions and renovations, as we explain in greater detail shortly. Therefore, our regression model becomes:

$$(4) \quad \begin{aligned} \text{religious building}_{it} = & \alpha_i + \tau_t + \delta_i \cdot t + \sum_{h=0}^3 \beta_{-5h} \cdot \text{quake}_{-5h,it} \\ & + \sum_{h=0}^3 \gamma_{-5h} \cdot \text{bishop}_i \cdot \text{quake}_{-5h,it} + \varepsilon_{it}, \end{aligned}$$

where *religious building_{it}* equals 1 if a new church (or cathedral) was registered or a substantial improvement of an existing church (or cathedral) was carried out in city *i* and at time *t*. The other variables are already known from model (2). Because we are interested in estimating the differential effect of an earthquake on religiosity (and the bishop's ability to take advantage of it) in the sample used in our previous regressions, we only use cities in the period preceding their transition to a commune (if any).²⁵

The results are reported in Table VI for the three augmenting criteria, *polygon*, *epicenter*, and *circles*. Columns (1)–(3) refer to the CEI data set, columns (4)–(6) consider the extended data set for churches, and columns (7)–(9) show our output obtained on adopting the extended data set for churches and cathedrals.

The interpretation of the estimated coefficients is similar to that given for Table III: the β -coefficients refer to the effect of a

24. Before transitions, the average numbers of religious building events (including churches and cathedrals) are 0.017 and 0.006 in episcopal and non-episcopal see cities, respectively. In the first five years following an earthquake these averages become, respectively, in episcopal and non-episcopal see cities, 0.029 and 0.002 (*polygon* criterion), 0.025 and 0.005 (*epicenter* criterion), and 0.026 and 0.003 (*circles* criterion).

25. Note that our main results reported in Table III are robust when we only include the 97 cities employed in the estimation in this section.

seismic event on church building/ornamentation for the entire sample (episcopal and non-episcopal see cities), whereas the γ -coefficients capture the differential effect in episcopal see cities. Our results are consistent across data sets and imputation criteria. As will be seen, controlling for year fixed effects, city fixed effects, and city-specific time trends, in the first five years after an earthquake the β -coefficient is negative and (with only one exception) statistically significant at conventional levels, suggesting that the earthquake tends to retard or hinder the opening of new construction sites of religious buildings. One explanation is that a seismic event, besides influencing the religious beliefs, is likely to cause shocks to income or expectations on future streams of income, slowing the construction or the renovation of churches (and cathedrals). Importantly for our design, however, the estimated interaction effect between *earthquake* and *bishop* dummies in the first five years after an earthquake, the γ_0 coefficient, is positive and (most often) statistically significant, suggesting that in episcopal see cities the effect is of lesser magnitude with respect to cities that were not seats of a bishop. Furthermore, the estimated coefficient on the interaction term points to an effect of earthquakes on religious building events for episcopal see cities that is (with the opposite sign) equal to or greater than that for the non-episcopal cities. In Online Appendix A we also report our results obtained on using only data referring to entire buildings' constructions and excluding minor renovation works (Table A.4). Our conclusions remain substantially unchanged.

VI. CONCLUSION

In this article, we have documented that earthquakes retarded the transition to communal institutions in Italian cities ruled by religious-political leaders. We did not find such an effect for Italian cities ruled by feudal lords. Our explanation of these results hinges on the role of the religious leader in dealing with disorder after the crisis. In the Middle Ages, the Earth's tremors were mysterious and frightening events: they provoked panic, consternation, and disorder among the population. In a context of scant civic capital and substantial coordination problems, social order could only be restored by a strong leader. In the episcopal cities, the seismic events fortified the power of the bishops,

who were simultaneously political and religious leaders. Because earthquakes were perceived by the population as manifestations of God's wrath against men in our period of interest, they can be interpreted as shocks to people's religiosity that reinforced the authority of the incumbent religious-political leaders and consequently hampered institutional change. Our interpretation is supported by ancillary evidence, also presented herein, that points to a positive impact of earthquakes on religious beliefs. Alternative explanations of our findings seem not to be particularly compelling (from an empirical and historical point of view).

For example, an alternative explanation for the negative effect of earthquakes on the probability of transition to communal institutions is that after a seismic event, people devoted their time to rebuilding their properties, thus diverting resources from the process of institutional change. Although plausible, in our case this interpretation would not be consistent with two facts: first, the impact of an earthquake on the probability of an institutional transition to a commune holds for episcopal cities but not for cities that were not seats of a bishop; second, this effect operated even if the earthquake was only felt by people without causing any physical damage or deaths.

Our findings highlight the important role played by cultural factors, such as religiosity, in affecting institutional change, and they account for the observation that political institutions controlled by religiously connected leaders have historically proven to be stable. For instance, ancient Egypt under the rule of the pharaohs, China under the Han Dynasty, the Roman empire, the Papal State in central Italy until the late nineteenth century, the Meiji empire in Japan, and the ayatollah's supreme leadership in Iran were all long-lasting regimes in which the political leader and the religious leader were the same person. Some scholars have maintained that religion plays a crucial role in the resilience of political regimes (e.g., North, Wallis, and Weingast 2009). Niccolò Machiavelli (1532) argued that religiosity is able to support political stability and ensure social order. On discussing how the sovereign can ensure his power, Machiavelli drew a distinction between ecclesiastical and other principates: in the former, he stated, power is relatively easier to maintain, since the prince can rely on popular support based on religious feelings.

Although this article has focused on a particular historical episode, the mechanisms uncovered here may prove important in other historical contexts, and their implications call for further

investigation in broader settings. Of course, this contribution cannot shed full light on such vast phenomena, nor does it have any ambition to do so. Nonetheless, the findings point to the existence of mechanisms that, to the best of our knowledge, are still largely unexplored in the economic literature and have implications that warrant further exploration.
